An important element in the differential diagnosis of arsine poisoning is poisoning by stibine (SbH_3), the hydride gas of antimony. Stibine, a potent hemolytic agent that may cause signs and symptoms similar to those of arsine, is also liberated under similar occupational circumstances, such as contact of antimony-containing alloys or compounds with acidic solutions. Acute high-dose exposure to lead may result in a constellation of signs and symptoms that overlap with arsine poisoning, including acute central nervous system effects (headache or encephalopathy or both); abdominal pain; acute hemolysis; mild-to-moderate elevations in liver function tests; and short-term, mild-to-moderate renal insufficiency. The tempo of severe acute lead intoxication is seldom as rapid as that seen with acute arsine intoxication, however. The hemolysis associated with severe acute lead intoxication is not as extensive as that due to arsine, and the acute renal insufficiency is not a consequence of hemoglobin deposition or acute tubular necrosis. Certain stages of malaria due to infection with *Plasmodium falciparum* may resemble clinically arsine poisoning, with patients displaying hemolysis ("blackwater fever"), renal failure, gastrointestinal symptoms, and occasionally central nervous system symptoms. Patients with paroxysmal nocturnal hemoglobinuria may present with hemolysis and abdominal pain.

Treatment

Arsenic

The treatment of acute arsenic poisoning is summarized in Table 4.

Supportive Care and Decontamination

Treatment of acute arsenic poisoning requires supportive care (usually in the intensive care unit), possibly decontamination, and prompt use of specific chelating agents. Immediate supportive care should address the hypotension or incipient shock that often accompanies the increased vascular permeability and the gastrointestinal fluid loss from vomiting and diarrhea that is common in acute arsenic poisoning. Large volumes of

Table 4 Treatment of acute poisoning by inorganic arsenic

Supportive Care and Decontamination
Intravenous rehydration with crystalloid solutions
Vasopressor drugs
In patients with gastrointestinal fluid loss and hypotension, use as needed to support blood pressure and optimize urine output (≥ 1 mL/kg/h)
Sodium bicarbonate (as needed for severe metabolic acidosis)
Whole-bowel irrigation may be beneficial if there is a substantial amount of arsenic in the gut
<i>Avoid</i> phenothiazines and type 1a antiarrhythmics
Chelation^a
Agent of first choice: DMPS
(2,3-dimercaptopropanesulfonic acid, unithiol, Dimaval)
Administer intravenously 3–5 mg/kg every 4 h by slow infusion over 20 min
Agent of second choice if DMPS not immediately available: BAL
Administer intramuscularly 3–5 mg/kg every 4–6 h
When patient stable and able to absorb an oral medication, consider change to oral chelation with either
DMPS 4–8 mg/kg orally every 6 h
DMSA (2,3-dimercaptosuccinic acid, succimer):
7.5 mg/kg orally every 6 h, or 10 mg/kg every 8 h

^aDMPS and DMSA are not officially approved in all countries for chelation treatment of acute arsenic poisoning. Indications and dosages are the author's suggestion based on best available data

intravenous fluids may be needed to support blood pressure and maintain urine output. Moderate to high levels of urine output (1 mL/kg/h) are desirable because the kidney is the major route of arsenic excretion (Grade III recommendation). Because arsenic may result in congestive heart failure or noncardiogenic pulmonary edema, however, typically after several hours to days, determination of optimal fluid requirements ultimately may require invasive hemodynamic monitoring. Support with vasopressor agents, such as norepinephrine, or treatment of acidosis with bicarbonate may be indicated in severe cases. It may be prudent to avoid the use of phenothiazines as antiemetics or antipsychotics in these patients because these drugs may lower the seizure threshold or prolong the QT interval.

The potential development of malignant arrhythmias merits continuous cardiac monitoring

for at least the first 24–48 h in arsenic-poisoned patients who present with any initial electrocardiogram abnormality or whose other presenting symptoms or signs (e.g., gastrointestinal distress, hypotension, metabolic acidosis, or altered mental status) indicate significant acute intoxication. Monitoring beyond 48 h is indicated in patients with persistent symptoms or evidence of new (i.e., not preexisting) cardiovascular disturbances. These signs may include electrocardiogram abnormalities (e.g., tachycardia, ectopy, prolonged QT_c interval, U waves) or evidence of congestive heart failure, even to a mild degree. Antiarrhythmic drugs such as procainamide and other type 1a agents, which may exacerbate arsenic-related prolongation of the QT interval, should be avoided.

Indications for ICU Admission in Arsenic or Arsine Poisoning

Intensive care unit (ICU) admission is indicated for any patient with a history of acute ingestion of milligram quantities of inorganic arsenic or any patient with suspected arsenic ingestion who presents with overt signs of gastrointestinal, cardiovascular, or neurologic disturbance. Gastrointestinal manifestations, such as vomiting, diarrhea, or abdominal pain; cardiovascular findings, such as tachycardia or hypotension; or alterations in mental status, such as lethargy or agitation, may be followed abruptly by life-threatening shock, arrhythmias, or seizures.

Because of the potential for delayed cardiovascular or neurologic deterioration (congestive heart failure, noncardiogenic pulmonary edema, malignant arrhythmias, encephalopathy) continued ICU monitoring may be necessary for several days to a week after acute gastrointestinal symptoms or hypotension has been stabilized. Careful ongoing monitoring is indicated particularly in patients whose urinary arsenic concentration has been elevated markedly (e.g., >5000 $\mu\text{g/L}$ [66 $\mu\text{mol/L}$]) or in patients who exhibit prolongation of the QT_c interval on an electrocardiogram. Patients with

(continued)

arsenical peripheral neuropathy who display progressive signs of ascending motor weakness should be observed carefully for the abrupt appearance of neuromuscular respiratory failure.

Patients with known or suspected arsine intoxication should be admitted to the ICU, treated expectantly with vigorous intravenous hydration, and monitored carefully for progressive hemolysis and any compromise in cardiovascular, renal, or neurologic function. Because arsine-induced hemolysis may be associated with a latent interval of 2–24 h, patients who initially are asymptomatic still may merit careful overnight observation.

Gastrointestinal decontamination of retained arsenic is theoretically useful, but in practice the profuse vomiting that accompanies acute arsenic poisoning may obviate or preclude intervention. As noted previously, abdominal x-rays (and occasionally chest x-rays) may reveal the presence of radiopacities consistent with gastrointestinal retention of poorly dissolved arsenic. In these cases, it may be prudent to perform whole-bowel irrigation to hasten removal of this unabsorbed material [114, 138–142]. In one case in which a chemist deliberately ingested the massive quantity of 54 g of arsenic trioxide, intraoperative gastric lavage and endoscopy were unable to remove arsenic adherent to the gastric mucosa, and a gastrotomy was performed [67]. Colonoscopy and colonic irrigation have been used to remove poorly soluble arsenic that persisted in the proximal colon [67, 140]. Administration of oral activated charcoal often has been recommended, but because the binding affinity of activated charcoal for inorganic arsenic is extremely low *in vitro*, the clinical utility of this intervention is doubtful [143]. The detection of arsenic in human gastric aspirates 1 week after the last known ingestion raises the possibility that arsenic may undergo a degree of enterohepatic or enteroenteric circulation [14, 82], but the extent of this process has not been quantified, and a

potential approach to interdict it with alternative binding agents has not been studied in humans.

Hemodialysis may increase arsenic elimination in patients with marked oliguria or anuria secondary to arsenic-induced acute failure, but because of the rapid distribution of arsenic to extravascular compartments, the total amount removed by this route (on the order of a few milligrams) is miniscule compared with the amount responsible for the intoxication or the amount eliminated via the urine in nonoliguric patients [14, 47, 51, 144–146]. Because the oliguria associated with acute arsenic intoxication is generally due to hypotension and decreased renal blood flow rather than to acute tubular necrosis, fluid resuscitation to support blood pressure and maintain urine flow rates should be the focus of therapy (Grade II-3 recommendation). Hemodialysis or continuous veno-venous hemodiafiltration [54] should be considered only for patients with renal failure from another cause or patients whose oliguria or anuria is otherwise unresponsive.

Patients who develop delayed peripheral neuropathy should be monitored carefully for progressive involvement of the proximal musculature. There is a risk that neuromuscular respiratory failure might ensue abruptly when there is evidence of proximal limb weakness. Patients with this level of ascending motor involvement should undergo serial measurements of inspiratory muscle effort, and the possible requirement for mechanical ventilation on an emergent basis should be anticipated. Physical therapy is an important adjunctive measure in the recovery from arsenical neuropathy. Tricyclic antidepressants, such as amitriptyline, have efficacy in the treatment of neuropathic pain (Grade I recommendation) and thus may be of value in treating the painful dysesthesias that often occur in arsenic-induced peripheral neuropathy [147] (Grade III recommendation).

Chelation

The prompt use of chelating drugs in the treatment of acute arsenic poisoning is recommended. The value of this treatment is based on the results of animal experimentation, however, and the therapeutic efficacy of chelation has not been

established through carefully controlled human clinical trials [148]. The first chelating agent, dimercaprol (2,3-dimercaptopropanol), was developed by British scientists during World War II as a specific antidote for acute poisoning by the vesicant organoarsenical warfare agent lewisite [31, 149]. As noted earlier, dimercaprol often has been referred to as *British antilewisite* or *BAL*. Water-soluble analogues of dimercaprol, dimercaptopropanesulfonic acid (DMPS Unithiol, Dimaval), and dimercaptosuccinic acid (DMSA, succimer, Chemet) were developed as heavy metal chelators in the 1950s [150, 151] and offer the advantage of higher therapeutic index and delivery by oral and intravenous routes [152]. Animal experiments have shown that dimercaprol, DMPS, and DMSA increase survival in experimental animals administered lethal doses of arsenite [153, 154]. The effectiveness of chelation on survival declined, however, in proportion to the length of time after arsenic exposure that treatment was begun [153, 154]. In an early study of the effectiveness of chelation against poisoning by organoarsenicals in rabbits, a single dose of dimercaprol given within 5 min of the arsenical resulted in survival of all the test animals, compared with a zero survival rate when treatment was delayed for 6 h [155]. In humans exposed experimentally to low doses of diphenylcyanoarsine smoke, the percent increase in urinary arsenic excretion after dimercaprol was higher the sooner after exposure it was administered [156]. These experimental studies and limited clinical experience [62] suggest that chelation treatment begun within a few hours after acute arsenic ingestion offers an improved chance of a positive therapeutic outcome. Nevertheless, in many cases, death or delayed peripheral neuropathy has occurred despite prompt chelation treatment [14, 46, 48, 50, 66, 119, 157]. The clinical course of an incipient or established arsenical neuropathy, usually characterized by slow improvement over several months to years, generally is not influenced by chelation therapy [53, 62, 64, 70, 71]. Isolated case reports have associated chelation with more rapid resolution of arsenical neuropathy [158, 159], but because improvement would have been anticipated from the natural

history of the illness, the added therapeutic role of chelation in these cases cannot be determined.

Of the chelating agents currently available, DMPS has the most favorable profile for the treatment of acute poisoning by inorganic arsenic. Although available as a pharmaceutical agent (Unithiol; Oktyabr) in the Soviet Union since the 1960s and in Germany since the 1970s (Dimaval; Heyl), DMPS has become available only more recently in the United States. Since 1999, DMPS has been sold legally in the United States as a bulk drug substance available for use by compounding pharmacists [160].

DMPS offers several advantages over BAL the chelating agent traditionally used for the treatment of arsenic poisoning in the United States and the United Kingdom, since its introduction in the 1940s [161]. DMPS has a higher therapeutic index and potency ratio in the treatment of experimental acute arsenic poisoning in animals [152, 154, 162]. DMPS was more effective than dimercaprol in mobilizing and decreasing the arsenic content of numerous tissues in animal models. This increased effectiveness was particularly noteworthy in the brain, where dimercaprol resulted in an *increase* in arsenic content compared with a significant decrease after use of DMPS [152, 154, 163]. The water-soluble nature of DMPS enables it to be given intravenously, in contrast to BAL which is supplied dissolved in oil for administration by deep intramuscular injection only. The intravenous dosing available for DMPS allows more rapid delivery to the target tissues, especially in arsenic-poisoned patients who are hypotensive or in shock. In the therapeutic doses used to treat heavy metal poisoning, DMPS seems to be tolerated better than dimercaprol and in particular avoids the pain and discomfort associated with repeated intramuscular injections. Moreover, the administration of DMPS results in the formation of a DMPS-MMA^{III} complex, the only intact arsenic-chelator complex ever to be isolated in human urine [164, 165]. The clinical pharmacology of DMPS is discussed in detail in ► Chap. 168, “Unithiol.”

For patients in the initial stages of acute inorganic arsenic poisoning, DMPS is usually administered intravenously at total daily doses of

20–30 mg/kg/day. One sixth of the total daily dose every 4 h, or one-eighth of the total daily dose every 3 h, may be given by slow intravenous infusion over 20 min [166, 167]. Moore and associates [61] reported an initial intravenous dose of 5 mg/kg every 4 h; others have used or recommended a fixed dose of 250 mg (one 5 ml vial containing 50 mg/ml) every four hours [159, 165, 168, 169]. Continuous infusion of DMPS at an initial rate of 250 mg/h for 15 h, combined with high volume fluid administration, was used to treat an adult who presented with vomiting and abdominal pain 7 h after ingesting at least 1000 mg arsenic trioxide. Arsenic compounds totaling 987 mg (!) were recovered in the urine during that treatment interval [170].

Because it is important that chelation be started as soon as possible after arsenic ingestion, BAL should be used if DMPS is not immediately available (Grade II-3 recommendation). Dimercaprol is administered at doses of 3–5 mg/kg intramuscularly every 4–6 h. A switch from parenteral to oral chelation is appropriate when the patient has no signs of adverse gastrointestinal effects (e.g., nausea, vomiting, diarrhea, abdominal pain) and no signs of cardiovascular compromise (e.g., hypotension or decreased urine output), which might be associated with decreased absorption of medication administered through the oral route. Chelation can be continued with oral preparations of DMPS. An adult daily dose of 1.2–2.4 g administered in 12 divided increments has been recommended (i.e., 100–200 mg every 2 h) [171], but considering the elimination kinetics of DMPS [172], it is reasonable to administer a daily dose of 20 to 30 mg/kg/day in four divided doses (i.e. at 6 hour intervals).

The dimercapto chelating agent DMSA also can be used for treatment of arsenic poisoning when an oral agent is appropriate. DMSA has exhibited clinical efficacy and pharmacodynamic properties similar to those of DMPS in animal studies of acute arsenic intoxication [152, 154]. It can be administered at a total daily dose of 30 mg/kg/day. Although a dosing interval of every 8 h has been recommended for chronic lead intoxication, more frequent dose intervals (e.g., every 6 h) may be more appropriate for acute arsenic poisoning. The possibility that oral

chelation with DMPS or DMSA might increase absorption of arsenic retained in the intestinal tract has not been studied directly, but negative studies with other metals and these chelators suggest that enhanced absorption of arsenic is not likely to be a problem [173, 174]. D-Penicillamine has been shown to be ineffective in experimental arsenic intoxication [152, 175], and its use in human arsenic poisoning is not recommended. The clinical pharmacology of DMSA is discussed in ► Chap. 165, “Succimer.”

The optimal duration of chelation treatment for acute or subacute arsenic intoxication is not well established. In cases in which the intoxication is not rapidly lethal, hemodynamic stabilization and resolution of gastrointestinal symptoms may enable parenteral chelation to be switched to oral chelation after 2 or 3 days. It may then be appropriate to continue oral chelation at least until urine arsenic excretion decreases to less than 500 µg/24 h, or 400 µg/L (5 umol/L), urinary values that are lower than values associated with overt clinical effects in acutely exposed individuals. Alternatively, oral chelation might be continued until urinary arsenic excretion decreases to background levels (<50 µg/L [0.7 umol/L]), although the therapeutic benefit of extending chelation to this point is undetermined. A randomized, placebo-controlled clinical trial found no benefit of DMSA in the treatment of chronic arsenic poisoning in patients who already had been removed from ongoing exposure and whose urine arsenic levels were less than 50 µg/L [0.7 umol/L] [176].

Arsine

Prompt exchange transfusion of whole blood is a key therapeutic intervention in acute severe arsine poisoning. The value of exchange transfusion is supported by clinical reports [102, 135, 177, 178] and by mechanistic studies suggesting that the *in vivo* reaction of arsine with a hemoprotein, such as oxyhemoglobin, is an important step in the toxic effects of the gas [40, 43] (Grade III recommendation) [179]. Beneficial effects of exchange transfusion include (1) clearance from the blood of a toxic byproduct or complex formed

by arsine's reaction with hemoglobin; (2) removal of plasma hemoglobin or hemoglobin degradation products released by hemolysis, which then may precipitate in the renal tubules and cause acute tubular damage; and (3) restoration of a sufficient supply of intact erythrocytes to provide adequate oxygen delivery to the kidney and other tissues. A relatively simple technique of exchange transfusion in which whole donor blood is infused through a central line at the same rate of blood removal via a peripheral vein using a blood donor set has been described [180]. Other approaches have used modifications of hemodialysis circuits [181]. Exchange transfusion is recommended in any patient with suspected arsine poisoning exhibiting evidence of significant hemolysis. A plasma or serum hemoglobin level of 1.5 g/dL (15 g/L) or greater has been suggested as a level that merits this therapy [135], but given the delay inherent in securing the necessary donor blood, it would be prudent to plan for the implementation of exchange transfusion in patients with lesser but rapidly escalating plasma hemoglobin levels. Evidence of renal insufficiency or incipient acute tubular necrosis also is an indication for exchange transfusion in arsine-poisoned subjects. Prompt exchange transfusion in patients with arsine hemolysis may avert significant renal failure in some, albeit not all, cases [107, 135].

Maintenance of vigorous renal output with intravenous fluids and mannitol-induced osmotic diuresis also may be protective against hemoglobinuric renal failure and should be started promptly in all patients with evidence of hemolysis or significant arsine exposure (Grade III recommendation). Hemodialysis is indicated in cases of progressive oliguria and anuria. The toxic complexes or byproducts formed by the action of arsine on hemoglobin and other proteins in the blood may not be removed adequately by hemodialysis however [182], and hemodialysis should not be considered a substitute for exchange transfusion.

The value of chelating agents in the treatment of arsine poisoning is uncertain. In experimental arsine poisoning, 1 mM of BAL in human blood *in vitro* 5 min after exposure to arsine (2000 ppm) reduced observed hemolysis to 17% compared

with 33.3% in controls (i.e., a 50% decline in hemolysis) [183]. Although experiments with arsine-poisoned rabbits treated with dimercaprol within 30 min yielded a decline in observed lethality, the dose of BAL used was high, and the authors considered the observed results to be erratic [183]. A derivative of dimercaprol, 2,3-dimercaptopropyl ethyl ether, was more effective than dimercaprol in experimental studies of arsine poisoning, but further drug development was not pursued [183]. Soviet researchers reported that a highly lipid-soluble aryl thioether analogue of dimercaprol, 2,3-dimercaptopropyl-p-tolylsulfide (Mercaptide), was effective in experimental acute arsine poisoning in rats, whereas water-soluble DMPS was completely ineffective [184]. Rael and colleagues [40] found that preincubation of human erythrocytes with high concentrations of DMSA or DMPS *in vitro* diminished hemolysis after subsequent exposure to arsine. In human case reports of arsine poisoning, the administration of dimercaprol has not yielded clinical impressions of therapeutic efficacy [102, 185], but because clinical circumstances of poisoning and treatment are variable, little can be concluded from reports of this nature. It seems reasonable to initiate treatment with dimercaprol, a relatively lipid-soluble chelator, in patients who present in the early stages of acute arsine poisoning (i.e., within 24 h). Later in the course of poisoning, treatment with oral DMSA or DMPS may exert some benefit in countering the adverse effects of arsenite, which eventually is produced *in vivo* after arsine poisoning [136]. The treatment of acute arsine poisoning is summarized in Table 3.

Special Populations

Pregnant Patients

Transport of arsenic across the placenta has been documented in animal models [186] and confirmed in studies of pregnant women exposed to elevated concentrations of arsenic in drinking water [187]. The developmental toxicity of arsenic has been reviewed [26, 37, 188]. Animal

studies indicate that inorganic arsenic can cause malformations, prenatal fatality, and decreased fetal weight, usually at maternal exposures greater than 1 mg/kg/day [26]. Arsine exposure of pregnant rats and mice at concentrations of 0.025 ppm, 0.5 ppm, and 2.5 ppm resulted in increases in maternal spleen weight at the highest dose, but fetotoxicity was not observed [189]. A number of epidemiologic studies, including prospective cohort studies, have observed an adverse effect of environmental arsenic exposure on intrauterine growth and fetal and infant survival [190, 191].

Two reports of pregnant women acutely poisoned with inorganic arsenic showed transplacental transport resulting in fetal or neonatal death. A 17-year-old woman who was 30 weeks pregnant developed abdominal pain, vomiting, hypotension, and acidosis shortly after ingestion of approximately 400 mg of arsenic trioxide [192]. A single dose of BAL was given 24 h postingestion. The patient developed renal insufficiency and disorientation but subsequently recovered. A premature infant born 4 days after the arsenic ingestion had an Apgar score of 4 and hyaline membrane disease and died 11 h after delivery. Autopsy revealed elevated levels of arsenic in the infant's organs. A 39-year-old woman who was 28 weeks pregnant developed the acute onset of slight abdominal pain and hypotension after eating chocolate later found to contain a large amount of arsenic trioxide [55]. The mother survived after a stormy course that included cardiopulmonary failure and moderately severe peripheral neuropathy. Intrauterine fetal death was confirmed on day 5, and 3 days later a maternal urine arsenic concentration of 5800 µg/L (77 µmol/L) was reported. Examination of the organs of the aborted fetus revealed markedly elevated levels of arsenic.

The chelating agents DMPS and DMSA reduced, but did not eliminate, embryotoxic and teratogenic effects of sodium arsenite (12 mg/kg) in pregnant mice [193, 194]. The protective effects occurred only with high doses of the chelating agents (≥ 150 mg/kg), administered within 1 h of the arsenite. Nevertheless, these beneficial effects, combined with the apparent lack of adverse reproductive effects of the chelators

given alone at therapeutic doses, suggest that pregnancy should not be considered a contraindication to chelation with DMPS or DMSA in a patient with acute arsenic poisoning [195, 196].

Together with zinc and mercury, cadmium belongs to group IIb of the periodic table. It can be found in rocks, soil, water, coal, zinc ore, lead ore, and copper ore. In the environment, cadmium is present predominantly as the oxide or as the chloride, sulfide, or sulfate salt. It has no recognizable taste or odor. Cadmium sulfide, carbonate, and oxide salts are practically insoluble in water, whereas the sulfate, nitrate, and halides are soluble in water.

Cadmium is utilized widely in industry for the production of glass and metal alloys as well as many consumer products, such as batteries or pigments in plastics. Exposure to relatively high cadmium concentrations occurs predominantly in the workplace. Workers also can be exposed during welding and soldering. Cadmium oxide is the compound most frequently inhaled. Cadmium is also present in tobacco smoke.

Biochemistry and Kinetics

The major route of cadmium exposure for the nonoccupational setting and nonsmoking persons is via food (e.g., leafy vegetables or potatoes). Normal daily exposure is approximately 30 µg/day, of which about 1–3 µg/day is absorbed. In smokers, 2–6 µg/day can be absorbed. The smoke of one cigarette contains about 1–2 µg of cadmium.

In water, insoluble cadmium salts can be solubilized with changes in pH. Consequently,

This chapter was submitted shortly before the death of Dr. Meulenbelt, a sophisticated medical toxicologist, highly respected intensivist, and a great friend. He will be sorely missed.

insoluble cadmium compounds, such as cadmium oxide and carbonate, can dissolve at gastric pH. Iron deficiency increases cadmium absorption, whereas oral zinc supplements decrease its absorption [1]. Approximately 25% of cadmium administered with food is still retained after 3–5 days. Retention decreases to approximately 6% after about 20 days [2, 3]. Whole-body retention ranges from 1.2% to 7.6% (mean 2.7%) [4]. Following Satarug et al. a safe daily intake of cadmium should be kept below 25–30 $\mu\text{g/day}$ per person [5, 6]. The Permissible Exposure Limit, or PEL, which defines the limit to which an employee may be exposed to cadmium in the workplace is set at 5 $\mu\text{g}/\text{m}^3$ air [7]. The Separate Engineering Control Air Limit, or SECAL, apply to select and defined industries and processes, is 15 or 50 $\mu\text{g}/\text{m}^3$ for cadmium, depending on the processes involved [7].

Depending on the kind of cadmium compound and particle size, 50% of inhaled cadmium can be absorbed. Some authors stated that exposure to relatively more soluble compounds in biologic fluids seemed to be relatively more harmful [8, 9], but this was not confirmed by others [10]. The initial lung burden declines slowly after exposure [9, 11, 12]. Most inhaled or ingested cadmium is excreted in the feces. The excretion of cadmium via the kidneys is low.

Cadmium (+2) ions bind to anionic groups (especially sulfhydryl groups) in proteins (notably albumin and metallothionein) [13]. They are absorbed by the intestinal mucosa, after which a cadmium-metallothionein complex is transported to the target organs. Cadmium does not undergo any direct metabolic conversion, such as oxidation, reduction, or alkylation. The cadmium concentration in most tissues increases with age, especially in the kidneys and liver. The spleen, pancreas, and testes also contain relatively high concentrations after chronic cadmium exposure. After reviewing the literature, Kjellström and Nordberg [14] concluded that cadmium half-life in the kidney is 6–38 years (mean approximately 12 years) and in the liver is 4–19 years (mean approximately 7.5 years). Placental transfer of cadmium is slow and incomplete [15]. A kidney cadmium concentration of 50 $\mu\text{g}/\text{g}$ wet weight is a

maximum tolerable level in order to avoid abnormal kidney function [16]. This renal concentration corresponds to a urinary cadmium excretion of 2 $\mu\text{g}/\text{d}$ [5].

Clinical Presentation

Symptoms After Acute Exposure

Acute intoxication by inhalation of air with high cadmium levels rarely occurs except in cadmium welding, when exposure to high concentrations may cause severe pulmonary damage. During exposure, the symptoms are generally mild (comparable to symptoms seen in metal fume fever, such as cough, dyspnea, chest pain, and fever), but within a few days severe acute respiratory distress syndrome can develop, leading to respiratory failure, which can be fatal [17]. The lowest observed adverse effect level necessary in acute exposure to cause serious effects in humans seems to be 10 mg/m^3 . If a patient recovers from acute cadmium poisoning, the improvement seems to be rapid and complete. Limited data on follow-up after acute exposure are available.

Acute intoxication by ingestion may cause retrosternal pain (caused by esophageal irritation), nausea, vomiting, abdominal cramps, and diarrhea. Shock may be observed, which can be caused by fluid loss or cardiovascular depression or both. Ingestion of more than 150 g should be considered life threatening [18, 19].

Chronic Exposure

Cortona and colleagues [20] measured respiratory function parameters (forced expiratory volume, forced vital capacity, residual volume, and carbon monoxide diffusion) in 69 smoking and nonsmoking male subjects exposed for years to concentrations of 0.008–1.53 mg/m^3 of cadmium fumes in a factory producing cadmium alloys. In exposed workers, residual volume was more than 8% higher than in unexposed workers. In severely exposed workers, residual volume was increased by more than 10%.

Lung cancer risk also may be increased after long-term inhalational cadmium exposure. Stayner and coworkers [21] calculated that chronic exposure to 0.10 mg/m³ cadmium oxide dust or fume 7 days/week and 8 h/day may cause 50–111 excess lung cancer deaths per 1000 workers.

Eating or inhaling lower levels of cadmium for a long period may cause a high cadmium body burden, which may result in renal damage. The kidney is the main target organ of cadmium toxicity, particularly the proximal tubules. Although intracellular metallothionein is induced by cadmium, offering partial protection, nephrotoxicity may occur at times when this protection is insufficient. Cadmium not bound to metallothionein presumably is responsible for the cadmium-related tissue injury. The mechanism of kidney damage is not fully understood. The role of zinc transporters, calcium transporters, divalent metal-ion transporter-1, and metallothioneins in the accumulation of cadmium in the kidney cell is nicely reviewed by Yang and Shu [22]. The early stages of cadmium-induced proximal tubule injury may involve specific changes in cell-cell adhesion, cellular signaling pathways, and autophagic responses, which occur before the onset of necrosis and apoptosis [23]. The lowest observed adverse effect level for chronic inhalational exposure causing renal effects in humans has been reported to be 0.05–0.1 mg/m³, and the no-effect level is 0.02–0.05 mg/m³ [24–27]. Proteinuria has been reported at inhalational exposure levels of 0.067 or 0.0379 mg/m³ [28, 29].

There is no convincing evidence that cadmium causes hypertension. There is weak support that increased cadmium body burden may alter central nervous system function as evaluated by neuropsychologic tests [30]. A modest difference was found between cadmium-exposed and nonexposed workers in attention, psychomotor speed, and memory tests.

Cadmium exposure has been shown to alter zinc, iron, and copper metabolism, causing deficiencies of these trace elements [31]. Cadmium also influences selenium metabolism, inducing reduction in the activity of the selenoenzyme glutathione peroxidase [32].

Cadmium affects calcium metabolism. Painful bone disorders, including osteomalacia, osteoporosis, and spontaneous bone fractures, have been reported in persons chronically exposed to cadmium in food (e.g., itai-itai disease) [33, 34]. Dietary deficiencies of calcium, protein, and vitamin D are likely to account for increased susceptibility to bone effects after cadmium exposure [35]. Cadmium-exposed people exhibit a progressive disturbance in renal metabolism of vitamin D to its biologically active form [16, 36, 37]. Cadmium exposure is associated with risk of renal stones [38, 39]. Mason and associates [40] reported decreased renal reabsorption of calcium among cadmium alloy workers. This decreased calcium reabsorption is presumably responsible for the higher risk of renal stones in cadmium-exposed persons.

Diagnosis

Cadmium can be measured in blood, urine, hair, and nails. The blood concentration of cadmium is the best indicator of recent exposure [41, 42]. Urinary excretion of cadmium correlates with body burden and renal damage [41, 42]. Cadmium-exposed persons with proteinuria generally have increased cadmium excretion. The urine cadmium excretion may decrease, however, if renal damage is severe [15]. Hair and nails are less reliable because they can be contaminated easily. Within 1 day after exposure, the cadmium in blood is contained mainly in the red blood cells, and the plasma concentration may be low [43]. Whole-blood cadmium concentrations normally range from 0.4 to 1 µg/L (approximately 4–9 nmol/L) for nonsmokers and 1.4–4 µg/L (approximately 13–36 nmol/L) for smokers [13]. Whole-blood cadmium concentrations of 10 µg/L (approximately 89 nmol/L) are considered acceptable for occupational exposures [44]. The urine cadmium concentration is normally less than 1 µg/g of creatinine (approximately 1 nmol/mmol of creatinine) [13]. The average urine cadmium concentration is 0.35 µg/g of creatinine (approximately 0.35 nmol/mmol of creatinine) in nonsmokers; levels greater than 2 µg/g of creatinine (approximately 2 nmol/mmol of creatinine) are rare.

Proximal renal tubular damage can be diagnosed by increased concentrations of low-molecular-weight proteins in the urine. The leakage of these proteins is not specific for cadmium toxicity but is a marker of proximal tubular damage. These proteins, such as β_2 -microglobulin, light-chain immunoglobulins, retinol-binding protein, lysosomal enzyme *N*-acetyl- β -D-glucosaminidase (NAG), and ribonuclease, are filtered by the glomerulus and normally reabsorbed in the proximal tubules of the kidney. When kidney injury is present, the reabsorption of these low-molecular-weight proteins is hampered. NAG and β_2 -microglobulin are the most commonly used biomarkers of cadmium-induced proximal tubule injury. Of these, NAG is more sensitive. A novel marker that has shown promise in preclinical studies is kidney injury molecule-1 (KIM-1). KIM-1 is a transmembrane protein that is not detectable in normal kidney but is expressed at high levels in the proximal tubule after ischemic or toxic injury. Urinary KIM-1 serves as an earlier diagnostic indicator of kidney injury when compared with any of the conventional biomarkers [45]. In severe kidney damage, high-molecular-weight proteins, such as albumin, also can be detected in urine. Decreased reabsorption of amino acids or glucose may be more sensitive for tubular dysfunction than the leakage of low-molecular-weight proteins.

Treatment

Acute Exposure

Therapy should begin by removal of the subject from the exposure. There is inadequate documentation on the usefulness of gastrointestinal decontamination in the case of ingestion of cadmium. Activated charcoal has no proven benefit after cadmium exposure. Hemodialysis and hemoperfusion are not useful in the treatment of cadmium intoxication. In cases of severe renal damage, hemodialysis is useful to replace kidney function.

In acute cadmium poisoning, chelation efficacy depends on the chelating agent used, the molar ratio between the chelator and cadmium

(Cd^{2+}), the route of exposure, and the time elapsed between exposure and the initiation of therapy. Sodium calcium edetate (EDTA), penicillamine, and British antilewisite have been used, but these seem to be of limited value and may increase kidney burden and damage [46]. Andersen [47, 48] reported that 2,3-dimercaptosuccinic acid (DMSA) was effective in acute cadmium poisoning in mice. DMSA and 2,3-dimercapto-1-propane sulfonate (DMPS) were effective in reducing mortality and reducing cadmium burden in liver and kidneys in cadmium-intoxicated mice [49, 50]. DMPS is also active intracellularly; DMSA is not. Chelation therapy for acute cadmium exposure may be useful, but this needs to be confirmed in human clinical practice. Doses of DMSA or DMPS normally used during the chelation of other heavy metals should be used (see ► Chaps. 165, “Succimer,” and ► 168, “Unithiol”, respectively, for a further discussion of these agents).

Indications for ICU Admission in Cadmium Poisoning

- Acute inhalational exposure with respiratory failure due to pneumonitis, pulmonary edema, or both
- Severe metabolic disturbances due to renal failure from chronic exposures

Chronic Exposure

The treatment of chronic cadmium poisonings is complicated by the difficulty in evaluating the body burden and the lack of data regarding chelating agents in this setting [51]. At present, chelation generally is not advised for chronic cadmium exposure. DMPS and DMSA may decrease cadmium body burden effectively. It has not been established, however, whether this therapy would decrease cadmium-induced end-organ toxicity and advice should be sought from a medical toxicologist on a case-by-case basis.

In chronic cadmium exposure, removal from exposure is of fundamental importance. Adequate

occupational hygiene, environmental monitoring, and worker surveillance are important to limit occupational vapor exposure.

Criteria for ICU Discharge in Cadmium

Poisoning

- Patient weaned from the mechanical ventilator
- Metabolic disorder mainly corrected

Key Points in Cadmium Poisoning

1. Cadmium accumulates in the body.
2. The kidney is the main target organ.
3. Measure whole-blood cadmium concentration to validate acute exposure.
4. Measure urine cadmium concentration to validate chronic exposure and increased body burden.
5. Treatment is primarily supportive.
6. The efficacy of chelation therapy is not proven.
7. In chronic cadmium exposure, be aware of osteomalacia and osteoporosis (itai-itai disease).
8. Chronic cadmium exposure is associated with risk of renal stones.

Lead poisoning is one of the oldest intoxications known to medicine. The ancient Greek physician Galen warned that consumption of water transported through lead pipes rendered individuals “subject to disorders in the intestines” [1]. In 200 BC, Nikander of Colophon wrote that exposure to the lead oxide litharge could cause “deadly disturbances of the bowels, which, attacking with pains unexpected, overpower mankind” [2]. More than two millennia later, lead poisoning continues to be a major issue in environmental and occupational health. Although reductions in high-dose exposure have shifted the focus of public health concern to the effects of chronic low-dose exposure, overt, symptomatic lead intoxication continues to arise in a diversity of settings. In industry, it occurs predominantly in tasks associated with high-level exposure to lead dust or fume, such as welding or torch cutting of painted metal during construction or demolition, grinding or sandblasting of lead-coated surfaces, lead ore or zinc ore mining, smelting or refining of lead ores or scrap metal, repair of automotive radiators, use of powdered lead additives in fabrication of plastic, and manufacturing or recycling of lead storage batteries [3, 4]. In environmental settings, high-dose lead exposure may result from use of oral folk remedies or tonics that contain large amounts of lead (e.g., azarcon, greta, paylooah), consumption of illicitly distilled alcohol (moonshine), pica ingestion by children of lead-contaminated paint chips or lead objects, residential remodeling or repainting, and consumption of food or beverages prepared or stored in lead-glazed ceramics or lead-containing vessels. Fatal lead encephalopathy has resulted from the partial dissolution of retained lead bullets or shotgun pellets [5]. This process occurs primarily when the bullet, pellet, or lead fragment has lodged in or migrated to or is adjacent to a joint space or pseudocyst.

Chemistry and Pharmacokinetics

Lead is a soft, ductile, heavy metal that is obtained from the primary smelting of lead-containing ores, such as galena (lead sulfide) or cerussite (PbCO_3), or from the secondary smelting of

recycled lead scrap. The potential for lead intoxication is highest after inhalation or ingestion of lead that is in a soluble and readily absorbable form. These forms include fume, particulate, and glaze composed of lead oxides (litharge, red lead [Pb_3O_4]); dust or particulate composed of basic lead carbonate (white lead [$\text{Pb}(\text{OH})_2 \cdot 2\text{PbCO}_3$]), lead sulfate, or lead acetate; and solutions containing dissolved lead cations. Lead products of lower solubility, such as elemental lead, lead chromate, or lead sulfide, pose less acute risk but still may result in toxicity if the absorbed dose is high or if factors such as fine particle size, prolonged gut retention, or intraarticular contact promote in vivo dissolution. Organolead compounds, such as the oily liquid, tetraethyl lead, still used as an additive in certain aviation gasolines, are slightly soluble in water but are well absorbed by dermal, oral, and inhalational routes.

Pharmacokinetics of Inorganic Lead Volume of Distribution

Because of the affinity of lead for proteins in the erythrocyte, the initial volume of distribution of lead is low. After intravenous injection of a lead isotope to human volunteers, approximately 70–80% of the dose is present in whole blood at 7 h, and approximately 24% remains in whole blood at 20 days [6–8]. This time-dependent intravascular retention corresponds to a volume of distribution of 0.1–0.2 L/kg. With the passage of time, lead that is not excreted is redistributed predominantly to bone. Toxicokinetic studies in humans consuming stable lead isotopes over a period of months indicated that approximately 1% of lead is found in blood [9], which is consistent with a final volume of distribution of approximately 7 L/kg.

Protein Binding

At low-to-moderate concentrations of lead in whole blood, >99% of the lead is associated with the erythrocyte. The fraction of lead in the plasma increases nonlinearly with dose and may reach a few percentage points as whole-

(continued)

blood lead concentrations become $>80\text{--}100\text{ }\mu\text{g/dL}$ ($>3.9\text{--}4.8\text{ }\mu\text{mol/L}$) [10, 11]. The polymorphic enzyme δ -aminolevulinic acid dehydratase is the principal binding site for erythrocyte lead [11], and genetic polymorphisms in δ -aminolevulinic acid dehydratase seem to influence the toxicokinetics of lead and susceptibility to its toxic effects [12, 13]. Most plasma lead is protein bound, and only approximately 15% of the plasma lead is ultrafilterable [14].

Mechanisms of Clearance

Approximately 70% of total lead clearance occurs through the urine, with the balance excreted mostly in the feces and to a minor extent in sweat, hair, and nails [9, 14, 15]. Clearance from the blood is greater after acute exposure than with chronic exposure; in both cases, clearance increases exponentially with increasing blood lead concentration. After chronic exposure, urinary clearance of lead from the blood of adults has ranged from approximately 0.08 L/day at low blood lead concentrations to 0.3 L/day at high blood lead concentrations [14]. The overall temporal pattern of decline in blood lead concentration after removal from chronic lead exposure may be characterized by a multicompartiment kinetic model, composed predominantly of a fast compartment in the blood and soft tissues (half-time 1–2 months) and slower compartments in the skeleton (half-times of years to decades).

Active Metabolites

There are no known active metabolites.

Methods to Enhance Clearance

In lead-poisoned patients, chelation with chelating agents such as calcium EDTA or succimer initially may increase the rate of daily urinary lead excretion by 10-fold to 50-fold [16–23]. There is no role for enhancement of clearance by extracorporeal methods in patients with intact renal function. In patients with severe renal insufficiency, clearance may be increased by calcium EDTA chelation combined with hemofiltration or dialysis (see text).

Pathophysiology

Lead exerts a wide range of toxic effects involving multiple organ systems. The expression of lead toxicity is influenced by several factors, including the tempo and magnitude of the dose; the target organ; and the nutritional, genetic, and developmental characteristics of the host. On a biochemical level, many of the key effects of lead are mediated by interference with essential cations, particularly calcium, and interaction with enzymes and other proteins. Lead mimics or inhibits multiple cellular actions of calcium and alters calcium flux across membranes, ultimately increasing levels of cytoplasmic calcium in many cell types [24, 25]. Increases in intracellular calcium in cerebrovascular endothelium may disturb microfilaments or other cellular components responsible for the integrity of tight junctions and contribute to cerebral edema [26]. Damage to brain capillaries and interstitial edema of white matter, particularly in the cerebellum, are a histopathologic feature of lead encephalopathy [27, 28]. The increased susceptibility of juvenile animals to lead encephalopathy may be in part a consequence of the diminished ability of immature brain astrocytes to sequester lead [29].

Lead's interaction with calcium flux seems partly responsible for its myriad effects on central and peripheral neurotransmission [24]. Alterations in synaptic transmission at the neuromuscular junction of visceral smooth muscle may underlie the disordered intestinal motility and tone that occurs during lead colic [30, 31]. At low concentrations, lead can substitute for calcium in the activation of protein kinase C, which contributes to lead's amplification of glutamate-induced oxidative stress in the brain and other tissues [32]. In some neuronal cells, lead interacts with calcium-sensitive mitochondrial permeability transition pores, which results in mitochondrial depolarization and the initiation of the cytochrome-*c*–caspase cascade of apoptosis [33].

Lead's disruption of mitochondrial membranes also may contribute to the diminished incorporation of iron into protoporphyrin IX, which is a feature of lead-induced anemia. Lead interferes

with the action of enzymes and other proteins through its affinity for diverse biochemical ligands, including sulfhydryl, phosphate, and carboxyl groups. It may alter the conformation of the zinc finger motifs that are integral to the function of many DNA binding proteins, enzymes, and receptors [34]. Lead avidly binds to and inhibits the heme synthesis enzyme δ -aminolevulinic acid dehydratase. This action not only contributes to deficits in heme synthesis but also results in accumulation of heme precursors, such as aminolevulinic acid, that may have direct or indirect neurotoxic properties [35]. Lead's ability to be a potent agonist of calcium in its activation of calmodulin and protein kinase C affects multiple aspects of signal transduction. The potential for numerous additional biochemical modes of action has been documented and is the subject of ongoing research investigations. The complex interplay of these effects, which range from subtle alterations in cell signaling to overt cytotoxicity, are paralleled by the diverse manifestations of human lead intoxication.

Clinical Presentation and Life-Threatening Complications

The adverse health effects of lead include a broad spectrum of multisystemic effects, ranging from subclinical impacts on cognitive and cardiovascular function to overt, life-threatening clinical presentations. This chapter focuses on the manifestations of lead poisoning that always require acute, inpatient medical care: *lead encephalopathy* and *lead colic*. These conditions are associated with high-dose lead exposure and blood lead concentrations that usually are greater than 80–100 $\mu\text{g/dL}$ (>3.9 – 4.8 $\mu\text{mol/L}$). As a result of preventive public health measures, these severe effects are now a relatively rare presentation of lead intoxication in North America and Europe, but there continue to be outbreaks of severe lead poisoning in other areas of the world [36, 37].

Lead Encephalopathy

Lead encephalopathy is a potentially life-threatening disturbance of central nervous system function associated with an altered sensorium, ataxia or incoordination, seizures, and coma. Because lead encephalopathy usually occurs in the context of recurrent lead exposure and a progressive increase in blood lead concentration, it often is preceded by several weeks or more of prodromal neurologic and constitutional symptoms, including severe headache, fatigue, sleep disturbance, anorexia, irritability, or loss of libido. Although rare, lead encephalopathy may occur after a single high-dose lead exposure [38]. An altered level of consciousness, which is expressed variably as delirium, hallucinations, lethargy, or stupor, may follow abruptly the prodromal symptoms. Isolated or recurrent seizures are common, affecting three quarters of the subjects in one survey [39]. Generalized seizures are most typical, but focal motor seizures also may occur. In some cases, convulsions may precede any evidence of an altered sensorium. Delirium, when it occurs, may persist or intensify over days to a week, even after the patient has been removed from lead exposure. Rarely the encephalopathic patient may lapse into a coma, and death may occur in the setting of progressive cerebral edema and increased intracranial pressure.

In children exposed acutely or recurrently to large doses of lead, the appearance of lead encephalopathy usually is preceded by 1 or more weeks of antecedent symptoms, which may include headache, lethargy, anorexia, vomiting, clumsiness, ataxia, and gait disturbance. In incipient cases, there may be evidence of a recent decline in visual acuity, and reversible blindness has rarely occurred in children and adults [40, 41]. In all age groups, the classic lead-related gastrointestinal effects of colic (see later) and constipation do not always precede or accompany the emergence of even florid encephalopathy [42, 43].

The neurologic examination in lead encephalopathy is variable. Despite presentation with an altered sensorium or a history of recent

convulsions, the patient may have no apparent neurologic deficits at the time of examination. In other cases, a wide variety of positive findings may be present. Reports have noted hyporeflexia and flaccidity [44, 45] and hyperreflexia and hypertonia [46–48]. When present, ataxia frequently has been characterized as central or truncal, and an unsteady gait occasionally may be a prominent feature [49, 50]. In a few cases, there may be lateralizing findings, such as hemiparesis [39, 51–54]. There may be recent-onset strabismus, and cranial nerve palsies affecting the third or sixth cranial nerves have been noted, usually in conjunction with evidence of increased intracranial pressure [43, 44, 46, 53, 55]. Facial nerve (cranial nerve VII) palsy also may occur [44, 54, 56]. Papilledema, with or without retinal hemorrhages, was a rare finding in a series of adults with lead encephalopathy, most of whom survived [39]. Papilledema was more common with fatal lead encephalopathy in children [51], but it is a finding with low sensitivity and negative predictive value. Bulging and tense anterior fontanelles may be present on physical examination of infants with lead-induced cerebral edema and elevated intracranial pressure.

Lead Colic

Although lead colic is not life-threatening, it manifests as severe abdominal pain and usually warrants intensive care for prompt parenteral chelation, pain control, and monitoring for the possible development of lead encephalopathy. Painful lead colic generally emerges in patients with blood lead concentrations greater than 80 µg/dL (>3.9 µmol/L). Milder, nonspecific gastrointestinal discomfort and constipation may appear at blood lead concentrations greater than 60 µg/dL (>2.9 µmol/L) in some individuals. The clinical presentation of lead colic was described extensively by Tanquerel des Planches and Dana [57], who attended to 1217 cases of this disorder over 8 years. More than a century and half since its

publication, Tanquerel des Planches' classic treatise on lead diseases remains unparalleled for the detail of its bedside observations and the extent of the case material. Tanquerel des Planches [57] observed the following:

This colic pain generally consists of a violent twisting sensation. In other cases less numerous it is an acute feeling of dilacerations, tearing out, pricking, burning, boring. Sometimes this increase of sensibility is compared by the patient to a simple constriction, or rather compression, produced by a weight upon the abdomen. In this last case the abdominal pains are generally obtuse, and their progress continues to be nearly uniform. In all other cases the pain is so intense that it throws the patient into the greatest agitation, but then it is not always the same; it becomes more severe by fits, either by day or by night.

As noted further by Tanquerel des Planches [57] and other experienced observers [58], the paroxysms of pain last minutes to hours and may recur at widely variable intervals, ranging from minutes to days. The pain typically is midline but may shift superiorly or inferiorly between bouts. Obstinate constipation is almost always present ($>90\%$ of cases), often resulting in a cessation of bowel movements for several days. Rarely a patient either may maintain a normal bowel pattern or may experience diarrhea. As observed by Tanquerel des Planches [57], the abdomen is retracted in approximately half of cases of active colic, and in approximately two thirds of affected patients the pain is diminished by application of external pressure or palpation. Patients frequently press on their abdomens with both hands or shift to a prone position in a restless attempt to obtain relief. Abdominal tenderness to palpation occurs but is rare. Borborygmus was noted in three fourths of Tanquerel des Planches' cases, and vomiting occurred in one third. Despite the pain, the pulse is notably slow. The heart rate ranged from 30 to 60 beats/min in approximately 55% of the painful episodes observed by Tanquerel des Planches [57]. Blood pressure may be increased. Fever usually is absent. Although patients may be distraught and distracted by the intense pain, their sensorium usually is intact.

Other Clinical Features in Overt Lead Intoxication

Additional lead-induced medical problems may complicate the clinical presentation of lead encephalopathy or lead colic but seldom are the sole basis for inpatient medical attention. High-dose lead exposure that is chronic, but occasionally acute, may result in a predominantly *motor* polyneuropathy. Overtly affected individuals usually have blood lead concentrations greater than 80–100 µg/dL (>3.9 – 4.8 µmol/L). The classic presentation begins with weakness of the extensors of the fingers and wrists (wristdrop), but variants that primarily involve the extensors of the toes and feet or the shoulder girdle also may occur [58–60]. In chronic cases, there may be antecedent tremor. Patients with advanced neuropathy may note decreased sensation, but painful dysesthesias are absent. Patients with months to years of blood lead concentrations greater than 80–100 µg/dL (>3.9 – 4.8 µmol/L) may become emaciated and cachectic.

Rarely, jaundice may develop after acute or subacute high-dose exposure [58, 61–63], usually in association with hemolysis and indirect hyperbilirubinemia. Tanquerel des Planches [57] described the jaundice caused by heavy lead exposure to be an “earthy yellow” that was less green and bright than “common jaundice,” which he presumably associated with infectious hepatitis.

In patients with poor oral hygiene, hydrogen sulfide released by the action of oral microbes present in the gingival sulcus may react with lead in the gingival circulation to form lead sulfide [64]. This precipitate may appear as a darkly pigmented blue-gray line a few millimeters wide at the gingival margins. Although the presence of a gingival “lead line” sometimes may provide a useful clue to the presence of lead poisoning, it has low sensitivity as a diagnostic finding, as it may be absent in individuals with good oral hygiene or brief exposure [58].

Patients with chronic elevation of blood lead concentrations greater than 40–50 µg/dL (>1.9 – 2.4 µmol/L) may complain of prominent arthralgia and myalgia without evidence of localized synovitis or tenderness [65, 66]. Lead-

induced chronic renal insufficiency is associated with an increased risk of gout and gouty arthritis, a consequence of decreased renal clearance of uric acid [67–69]. As noted further subsequently, laboratory tests in a patient with overt lead poisoning frequently reveal hematologic abnormalities and less commonly renal dysfunction. Problems associated with lower-dose lead exposure, such as a history of hypertension, neuropsychologic dysfunction, developmental delay, and adverse reproductive outcome, also may be present in a patient who presents with lead colic or lead encephalopathy.

Diagnosis

Rapid, Nonspecific Diagnostic Tests

Several readily available laboratory and radiographic tests can assist in the diagnosis of overt lead intoxication. Patients with lead encephalopathy or lead colic usually have evidence of anemia on the complete blood count. The anemia may be a consequence of hemolysis associated with acute or subacute high-dose exposure [61, 63], but more commonly there is the gradual onset of a hypochromic anemia with normocytic or microcytic indices. The microcytosis often may be related to coexistent iron deficiency [70]. Iron deficiency acts synergistically with lead in depressing heme synthesis [71], and it may increase the risk of lead intoxication by enhancing gastrointestinal lead absorption [72]. Examination of the peripheral blood smear may reveal erythrocytes with basophilic stippling. The stippling is due to aggregation of ribosomal fragments in the maturing erythrocyte, possibly as a consequence of lead-induced inhibition of ribonuclease activity [73]. Basophilic stippling has been found within 3–4 days of acute, high-dose lead exposure [74, 75], and it may precede the appearance of anemia [38, 76]. The number of stippled cells sometimes increases steeply within 1–3 days after the onset of lead colic [76]. Although basophilic stippling of erythrocytes may serve as an important diagnostic clue to the presence of lead intoxication, it is neither a sensitive nor a specific finding. It also

can occur in other illnesses associated with hematologic effects, including arsenic poisoning, benzene exposure, thalassemia, and certain types of cancer.

Reticulocytosis is another hematologic finding that frequently but not invariably is present in patients with lead-induced anemia. Bone marrow examination may reveal either erythroid hyperplasia or hypoplasia, depending on whether the predominant hematologic impact has been hemolysis or suppression of erythropoiesis [77]. An increase in marrow ringed sideroblasts also may be observed. In adults, anemia due to lead exposure generally emerges at blood lead concentrations greater than 50–60 $\mu\text{g/dL}$ (>2.4 – 2.9 $\mu\text{mol/L}$), but in children an increased prevalence of anemia has been found with blood lead concentrations greater than 25 $\mu\text{g/dL}$ (>1.2 $\mu\text{mol/L}$) [78, 79].

Other common, rapidly available laboratory tests are affected less consistently by overt lead intoxication. Transitory azotemia, possibly a consequence of intrarenal vasoconstriction, may accompany lead colic [63, 80]. This condition causes moderate increases in blood urea nitrogen and serum creatinine that typically resolve within 1 month or less. The urine might transiently reveal increased cellularity on urinalysis [74, 80], but it is often entirely normal [81]. Children with high-dose lead exposure may develop a reversible Fanconi syndrome characterized by aminoaciduria, glycosuria, and hypophosphatemia with relative hyperphosphaturia [82]. However, this tubular effect usually is not accompanied by diminished glomerular filtration rate or overt renal insufficiency. The reversible renal abnormalities of acute or subacute lead intoxication should be distinguished from the irreversible interstitial and peritubular fibrosis of chronic lead nephropathy, a relatively rare condition that may appear after years of high-dose lead exposure (i.e., blood lead concentrations >80 $\mu\text{g/dL}$ [>3.9 $\mu\text{mol/L}$]) [83].

Liver function tests in severe lead intoxication may be notable for mild-to-moderate elevations in serum transaminases [63, 73, 84]. The rare elevation in total bilirubin is usually a result of hemolysis, in which case the indirect (unconjugated) bilirubin fraction predominates.

The characteristic features of lumbar puncture in patients with lead encephalopathy are an elevated opening pressure, often greater than 300 mm H_2O , and an increased cerebrospinal fluid (CSF) protein count [39, 55]. The CSF white blood cell count may be normal or slightly elevated (usually <30 white blood cells/high-power field), resulting in a mild albuminocytologic dissociation.

Several radiologic studies may be helpful in the diagnosis and management of overt lead intoxication. In patients with lead encephalopathy, computed tomography or magnetic resonance imaging of the brain frequently shows evidence of diffuse cerebral edema (e.g., effacement of the cerebral gyri or symmetrically narrowed ventricles). Other, less common findings include focal cerebellar edema [45], which may cause compression of the fourth ventricle, and obstructive hydrocephalus [46, 48]. Asymmetric compression of a lateral ventricle has also been shown [85].

In children with a history of severe lead intoxication, plain radiographs of the skeleton may reveal dense, thick, transverse opacities at the metaphyseal ends of the bones. Commonly referred to as *radiographic lead lines*, these usually are best visualized at the ends of long bones, such as the tibia, fibula, femur, humerus, radius, or ulna. Lead lines also may be apparent at the iliac crests or the tips of the scapulae [86]. The opacities are not collections of “lead” but rather are bands of increased calcium deposition associated with lead-induced inhibition of calcified cartilage resorption. Although predominantly observed in children 2–6 years old [87], radiographic lead lines also may be visible in neonates and infants [48, 88]. Discrete lead lines migrate toward the diaphysis and eventually disappear as the child grows. They are not useful as markers of lead exposure in older children or adults. In one survey of 104 lead-poisoned children and 18 age-matched controls, the mean blood lead concentration of the children with lead lines was 49 ± 17.3 $\mu\text{g/dL}$ (2.4 ± 0.8 $\mu\text{mol/L}$) [89]. The authors of the survey suggested that the presence of a dense opacity in the proximal fibula may be helpful in distinguishing lead lines from bands that occur in physiologic sclerosis, particularly in children older than 3 years of age. Lead lines may be absent

in patients with severe childhood lead intoxication, particularly in the setting of recent, acute exposure. In addition, lead lines do not form at low levels of lead exposure that nonetheless may be of public health concern. Accordingly, radiographic lead lines should not be used to screen for or rule out childhood lead poisoning. Nevertheless, lead lines should increase the index of suspicion for lead poisoning in a child with consistent signs and symptoms and should prompt an investigation for potential lead exposure whenever they are observed as an incidental finding.

Plain radiographs of the abdomen may reveal flecks of a radiopaque substance or discrete lead-containing foreign bodies (e.g., fishing weights), in the gastrointestinal tract of children or adults who recently have ingested substantial amounts of lead [75, 86, 90]. Because finely suspended or highly soluble lead formulations may be poorly visualized, however, or because the nonabsorbed portion of the ingested lead may have been evacuated by the time of the examination, the absence of suspicious radiopacities on abdominal radiographs does not rule out a significant recent ingestion. In patients with acute lead colic, abdominal X-rays may reveal focal intestinal dilation [31, 91].

Blood Lead Concentration

The blood lead concentration is the most specific and useful diagnostic test for lead intoxication. Because greater than 95% of the lead in blood occurs in the erythrocyte, the measurement is conducted on whole blood rather than serum or plasma. Blood intended for clinical evaluation of potential lead intoxication should be collected in a special trace metal evacuated tube (e.g., royal blue top in the United States) containing a small amount of ethylenediaminetetraacetic acid (EDTA) or heparin as an anticoagulant. In situations in which such a tube is unavailable, blood collected in a standard complete blood count tube (e.g., lavender top in the United States) still may yield useful information. A commercially available point-of-care blood lead testing analyzer (LeadCare II), sometimes fielded in resource limited environments, quantifies blood lead

concentrations up to a maximum of 65 $\mu\text{g/dL}$ (3.1 $\mu\text{mol/L}$) and displays a reading of “HI” (high) for more elevated samples. A technique that dilutes such “high” blood samples with uncontaminated low level blood lead obtained from unexposed donors has recently enabled the LeadCare II instrument to be used in the quantitation of blood samples containing up to approximately 400 $\mu\text{g/dL}$ (19.3 $\mu\text{mol/L}$) lead [92]. In adults, the blood lead concentration in lead encephalopathy almost always is greater than 100 $\mu\text{g/dL}$ (>4.8 $\mu\text{mol/L}$), and it is common for such cases to present first with levels greater than 150 $\mu\text{g/dL}$ (>7.2 $\mu\text{mol/L}$). Children are more vulnerable to the central nervous system toxicity of lead, and blood lead concentrations greater than 70 $\mu\text{g/dL}$ (>3.3 $\mu\text{mol/L}$) are considered to pose a risk of encephalopathy [93]. The mean blood lead concentration was 330 $\mu\text{g/dL}$ (15.9 $\mu\text{mol/L}$) among a large series of children treated for lead encephalopathy in Baltimore between 1931 and 1970 (approximate range 90–800 $\mu\text{g/dL}$ [4.3–38.6 $\mu\text{mol/L}$]) [94, 95]. The mean blood lead concentration of children who died as a result of lead poisoning in that series was similar (327 $\mu\text{g/dL}$ [15.6 $\mu\text{mol/L}$]). Among a large cohort of rural Nigerian children with elevated blood lead concentrations ($n = 972$), the odds ratio for severe neurological findings consistent with lead encephalopathy was 7.35 (95% CI 2.02–26.79) at a blood lead concentration of 100–119 $\mu\text{g/dL}$ compared to 45–64 $\mu\text{g/dL}$ and 23.96 (95% CI 7.33–78.31) at a blood lead concentration ≥ 120 $\mu\text{g/dL}$ [96]. Lead colic in adults usually occurs at blood lead concentrations greater than 80 $\mu\text{g/dL}$ (>3.9 $\mu\text{mol/L}$).

The time interval between the acquisition of an elevated blood lead concentration and the manifestation of overt symptoms is highly variable and depends in part on the tempo and intensity of the exposure and individual host factors. Exposure to massive doses of lead, which may occur with intentional oral overdose [74, 97, 98] or parenteral injection [99], may produce overt gastrointestinal or neurologic symptoms in a few hours. Individuals with acute, high-dose inhalational exposure to lead fume or dust have developed symptoms within a few days to a week [38, 61]. In one individual who ingested multiple metallic objects,

there was a documented lag time of at least 8 days between a blood lead concentration of 436 $\mu\text{g}/\text{dL}$ (21.1 $\mu\text{mol}/\text{L}$) and the development of lead encephalopathy [59]. In most cases, a patient with severe lead intoxication has been exposed to lead repeatedly over weeks to months or longer. Accordingly, most of the data linking a given blood lead concentration to a particular constellation of signs and symptoms have been derived from studies or cases in which the presumed exposure occurred in a chronic, subacute, or acute-on-chronic pattern.

The geometric mean blood lead concentration in the United States from 2011 to 2012 was estimated to be 0.973 $\mu\text{g}/\text{dL}$ (95% confidence interval 0.916–1.04 $\mu\text{g}/\text{dL}$) [100]. This represents an approximately 92% decline from the late 1970s, when the corresponding value was 12.8 $\mu\text{g}/\text{dL}$ (0.6 $\mu\text{mol}/\text{L}$) [101]. In 2012, the US Centers for Disease Control and Prevention recommended that a “reference value” blood lead concentration corresponding to the 97.5 percentile of US children age 1–5 years old assessed in the semi-annually updated National Report on Human Exposure to Environmental Chemicals be used to identify children with an elevated blood lead concentration. Blood lead concentrations across the range of 1–10 $\mu\text{g}/\text{dL}$, with no demonstrable no-effect threshold, have been associated with subclinical neurocognitive deficits in children [102, 103]. Children with a blood lead concentration equal to or greater than the reference value, which was 5 $\mu\text{g}/\text{dL}$ in 2012, should receive follow-up blood lead monitoring and investigation [104].

In all age groups, the magnitude of lead exposure and the concentration of lead in blood associated with the onset of symptomatic lead intoxication are characterized by a wide range of interindividual variability. The clinical presentation of a symptomatic patient with a high blood lead concentration is highly variable; some patients exhibit severe lead colic without any evidence of encephalopathy, whereas others with comparable blood lead levels may present with delirium and seizures without any history of gastrointestinal symptoms. Some adult or pediatric patients may be asymptomatic despite

blood lead concentrations greater than 100 $\mu\text{g}/\text{dL}$ ($>4.8 \mu\text{mol}/\text{L}$) [95]. In the recent Nigerian childhood lead poisoning epidemic associated with artisanal gold mining, 40 of 100 children with blood lead concentration at initial screening $\geq 120 \mu\text{g}/\text{dL}$ displayed no neurological features. The 97.5th percentile among the asymptomatic subset ($n = 885$ of 972 children all with blood lead concentration $\geq 45 \mu\text{g}/\text{dL}$ (2.2 $\mu\text{mol}/\text{L}$)) was 146 $\mu\text{g}/\text{dL}$ (5.8 $\mu\text{mol}/\text{L}$) [96]. This wide interindividual variability applies to the entire scope of lead-related pathology, including constitutional, neuropsychologic, and cardiovascular effects that may occur at lower exposure levels. The biologic basis for the variability in response is poorly understood but might relate in part to polymorphisms in endogenous lead binding proteins and other genetic factors [12].

Zinc Protoporphyrin and Other Indices of Lead Exposure

Lead inhibits the formation of heme by several mechanisms, including interference with the incorporation of reduced (ferrous) iron into protoporphyrin IX [105]. Zinc becomes incorporated into this precursor molecule instead, resulting in an accumulation of zinc protoporphyrin (ZPP) in developing erythrocytes. As erythrocytes with a normal concentration of heme disappear through senescence or hemolysis, there is a progressive increase in the blood concentration of ZPP or the ratio of ZPP to erythrocyte heme. In general, an elevation in ZPP greater than background levels becomes detectable within 2–6 weeks after the blood lead concentration becomes greater than 30 $\mu\text{g}/\text{dL}$ ($>1.4 \mu\text{mol}/\text{L}$). This lag time may provide information on the likely time course of a patient’s lead exposure. A high blood lead concentration in the presence of a normal ZPP suggests that the lead exposure began recently. Conversely, a high blood lead concentration with an elevated ZPP suggests that the lead exposure began more than 2 weeks ago, provided that the patient does not have another medical condition (e.g., iron deficiency or anemia of chronic disease) that also can elevate ZPP.

Measurement of the amount of lead excreted in the urine in the first 24 h after initiation of chelation may provide reassurance that a significant amount of lead has been mobilized, but as a practical matter diagnostic and management decisions should be guided primarily by the blood lead concentration. A qualitative urine “heavy metal screen” offered by some laboratories frequently is subject to false-negative results and should never be relied on to rule out lead poisoning [5]. Chelation challenge or provocation tests that measure the urinary excretion of lead after a single dose of a chelating agent, such as calcium EDTA, do not reliably reflect the major body burden of lead found in the skeleton or a patient’s long-term cumulative lead exposure [106–108]. At present, chelation challenge tests have not been validated as a means to identify patients who might derive therapeutic benefit from chelation, and their use for this purpose has been criticized [109]. Measurement of lead in bone by noninvasive x-ray fluorescence may be a useful biomarker of a patient’s long-term lead exposure, but it is not a tool for acute assessment.

Key Diagnostic Features and Differential Diagnosis

Lead encephalopathy should be considered in the differential diagnosis of patients who present with delirium or seizures and anemia. The coexistence of abdominal pain, constipation, and anemia should suggest the potential presence of lead colic. For both conditions, a history of antecedent constitutional or neurobehavioral symptoms (e.g., fatigue, lethargy, anorexia, irritability, myalgia, or headache) should increase the index of suspicion. Less commonly, there may be a concurrent history of ataxia, motor neuropathy, developmental delay (in children), or renal insufficiency or gout (in adults). Basophilic stippling of erythrocytes, a gingival lead line, and (in children) the presence of radiographic lead lines on the long bones are relatively specific clues; however, they are

insensitive findings and often are absent. Obtaining a careful environmental and occupational history is always indicated because it is likely to identify a potential source of lead exposure in many, albeit not all, cases. The ultimate diagnosis of lead poisoning should be confirmed by a sufficient elevation in blood lead concentration, but treatment for severe intoxication (see later) should not be withheld pending return of blood lead test results, which may take one or more days in many locations.

The differential diagnosis of lead encephalopathy includes a variety of infections of the central nervous system, particularly encephalitis, but also subacute meningitis and intracranial abscess. Similar to lead encephalopathy, these conditions can present with a history of headache, delirium, and seizures and can be accompanied by signs of increased intracranial pressure. Fever is often prominent in central nervous system infections but is relatively rare in lead encephalopathy. Lead encephalopathy is not associated with the CSF pleocytosis that is a feature of many central nervous system infections. Although some viral processes that cause encephalitis also may cause bone marrow depression, anemia is apt to be more common in patients with lead encephalopathy.

Patients in alcohol withdrawal can present with delirium and seizures and may have laboratory evidence of anemia and elevations in transaminases and serum bilirubin. Alcohol withdrawal generally does not cause cerebral edema, however, and patients in withdrawal usually display a hyperadrenergic state that is not a feature of lead encephalopathy. In contrast to the normocytic or microcytic anemia of lead poisoning, the anemia common in chronic alcoholism tends to be macrocytic. In certain cases, prominent cerebellar edema in lead encephalopathy can mimic a midline cerebellar tumor, and both conditions can present with signs of altered mental status and obstructive hydrocephalus. Lead encephalopathy sometimes causes lateralizing neurologic signs that resemble presentations of

subdural hematoma or focal brain edema from intracranial masses. These central nervous system lesions are not likely, however, to be accompanied by the anemia that often is found in patients with lead encephalopathy. Reye's syndrome is an encephalopathic process associated with vomiting, cerebral edema, and an acellular CSF. With rare exceptions [110], the hyperammonemia and severe liver dysfunction of Reye's syndrome are not features of lead encephalopathy. In contrast to Reye's syndrome, laboratory findings in lead encephalopathy include elevated CSF protein and anemia. Carbon monoxide poisoning can present with a history of headache, nausea, and vomiting progressing to altered mental status and convulsions, but the cerebral edema and anemia common to patients with lead encephalopathy are absent.

The differential diagnosis of lead colic includes other causes of severe abdominal pain, such as appendicitis, pelvic inflammatory disease, biliary colic, renal colic, intestinal obstruction, pancreatitis, and peptic ulcer. Gastrointestinal neoplasms can be associated with anemia, weight loss, and abdominal pain, although the pain generally is less severe and paroxysmal than that associated with lead colic. Attacks of acute intermittent porphyria and an even rarer condition, δ -aminolevulinic acid dehydratase deficiency porphyria, can share many of the features of severe acute lead intoxication, including colicky abdominal pain, constipation, nausea, and vomiting. In some cases, the gastrointestinal symptoms of porphyria are accompanied by neurologic derangements, including altered mental status, seizures, and motor neuropathy. However, severe lead intoxication is usually associated with a more profound anemia. The attacks of abdominal pain in lead colic often are accompanied by a slowing of the pulse rate, in contrast to the tachycardia of acute intermittent porphyria. A patient with sickle cell disease suffering a vaso-occlusive crisis may present with abdominal pain, joint pain, and anemia as well as altered mental status if acute CNS

vaso-occlusion is present. Although examination of the peripheral blood smear for characteristic sickle cells may facilitate the rapid diagnosis of sickle cell disease, care should be taken not to overlook the possible co-occurrence of severe lead intoxication in sickle cell disease patients [111]. CNS vaso-occlusive episodes are also more likely than lead encephalopathy to present with lateralizing neurological signs.

Treatment

Effective treatment of lead intoxication requires attention to decontamination, supportive care, and use of specific chelating drugs.

Decontamination

Ingestion of lead-containing material (e.g., paint chips, small lead weights or pellets, or lead-contaminated folk remedies or food) has been a common cause of severe lead poisoning in children and occasionally is the source of lead poisoning in adults. What visibly might appear to be a small quantity (e.g., a single paint chip, a sip of a lead-containing glaze, or a small lead fishing weight) may contain hundreds of milligrams of lead. Ingestion of lead pellets [112] and lead-based ceramic glaze [75, 113] has been associated with substantial increases in blood lead concentration within several hours. Partial dissolution of solid lead objects retained in the gastrointestinal tract has resulted in death within weeks [90, 114]. As noted earlier, radiopacities on abdominal X-rays may suggest the presence of retained gastrointestinal lead, but a negative radiograph does not rule it out. The possible presence of lead in the gastrointestinal tract should be considered in all children and many adults who present with symptomatic lead intoxication, and an aggressive approach to decontamination is indicated when there are positive radiographs or when recent ingestion is otherwise suspected.

Indications for ICU Admission in Lead Poisoning Suspected or Confirmed Lead Encephalopathy

History of potential lead exposure
 Altered level of consciousness (delirium, hallucinations, lethargy, stupor, coma)
 Seizure – focal or generalized
 Ataxia or gait disturbance (often absent)
 Prodromal symptoms of increasing headaches, lethargy, anorexia, vomiting, clumsiness, irritability, sleep disturbance; fever is uncommon

Neurologic examination findings consistent with increased intracranial pressure (often absent) – papilledema, cranial nerve palsies (especially cranial nerves III and VI), recent-onset strabismus, or decrease in visual acuity

Gingival lead line (helpful but often absent)

Neuroimaging consistent with increased intracranial pressure

Laboratory findings – anemia (common), basophilic stippling, indirect hyperbilirubinemia (rare), radiographic lead line (children only; helpful but insensitive), cerebrospinal fluid with elevated protein and relative acellularity

Blood lead concentration (whole blood) – usually $>100 \mu\text{g/dL}$ ($>4.8 \mu\text{mol/L}$) in adults, $>70 \mu\text{g/dL}$ ($>3.4 \mu\text{mol/L}$) in children

Lead Colic (Predominantly in Adults)

Severe, paroxysmal abdominal pain, often diminished by palpation, often with retraction of abdominal wall

History of severe constipation (common) or diarrhea (rare); nausea or vomiting

Slow or normal heart rate during episodes of abdominal pain

Blood concentration (whole blood) – usually $>80 \mu\text{g/dL}$ ($>3.9 \mu\text{mol/L}$)

Patients with lead encephalopathy or lead colic may present with other features of lead poisoning. In adults, these features may include motor predominant peripheral neuropathy, tremor, gout, hypertension, acute or chronic renal insufficiency, neuropsychologic

dysfunction (cognitive and behavioral), and history of adverse reproductive outcomes. In children, this may include developmental delay (neurocognitive, physical growth) and Fanconi-like renal syndrome. Because of the risk of incipient lead encephalopathy, intensive care unit admission should be considered for asymptomatic patients with extremely high blood lead concentrations ($>150 \mu\text{g/dL}$ [$>7.2 \mu\text{mol/L}$]).

Activated charcoal has relatively low affinity for many metal ions, and its potential value in reducing gastrointestinal absorption of inorganic lead is doubtful but unknown. Case reports suggest that whole-bowel irrigation may accelerate the elimination of gastrointestinal lead and diminish further absorption [115–117]. This process requires the administration of commercially available solutions of polyethylene glycol and electrolytes by mouth or per nasogastric tube at a rate of 20–30 mL/kg/h until a clear rectal effluent is achieved.

Although gastrointestinal decontamination may be desirable, many patients with symptomatic lead poisoning, particularly lead colic, have severe constipation that may limit the potential effectiveness of whole-bowel irrigation or cathartics. Suspected lead foreign bodies that exhibit prolonged radiographic retention in the gastrointestinal tract (i.e., >48 h), such as large intragastric objects or pellets lodged in the appendix, may require endoscopic or surgical removal [118–120].

Retention of lead-containing bullets, shotgun pellets, or other metallic projectiles poses a well-documented risk of severe lead poisoning when the location of the foreign body results in dissolution and systemic distribution of lead [5, 121]. The risk is greatest when the foreign body lodges or migrates into a joint space, where synovial fluid and mechanical factors accelerate breakdown of the object and dissolution of the lead [122, 123]. Severe lead poisoning also has been

reported when lead fragments have come in direct contact with bone or with fluid-filled spaces, such as paravertebral pseudocysts or a subscapular bursa [5, 124]. An isolated lead bullet fragment embedded in muscle or other soft tissue often becomes encased in fibrous tissue that permanently minimizes systemic lead exposure. Patients with retained lead bullets or projectiles who present with signs or symptoms of lead poisoning, or with high blood lead concentrations in the absence of clinical effects, should receive prompt supportive care and chelation to stabilize their condition and lower blood concentrations (see later). If radiographic evaluation determines that the retained objects are in or adjacent to a joint space, bursa, or pseudocyst or in direct contact with bone, surgical removal should be strongly considered. Successful arthroscopic extraction of a lead shotgun pellet from the knee joint has been reported [125]. Patients with retained lead foreign bodies without end organ effects and who have negligible or mild elevations in their blood lead concentrations require periodic monitoring for particle migration and blood lead elevation for at least the first year and possibly longer. Patient education and lifetime vigilance are warranted in all such cases because lead intoxication often insidiously or abruptly has emerged years to decades after the initial injury.

Health professionals involved in the diagnosis or care of a patient with lead poisoning should endeavor to have the source(s) of their patient's lead exposure investigated and controlled. Because overexposure to lead may be unrecognized or misdiagnosed, it is possible that a patient with confirmed lead intoxication may represent an "index case" indicative of unrecognized or ongoing overexposure to lead among family members, co-workers, neighbors, or other individuals in contact with the same or similar lead source(s). Employers and occupational and environmental public health agencies at the federal, state, or local level, including some with specific lead poisoning prevention programs, may be able to assist with exposure investigation and case management [126, 127].

Supportive Care

Lead encephalopathy is a medical emergency that requires management in an intensive care unit. Supportive care is targeted to three key objectives: (1) diminution or normalization of increased intracranial pressure, (2) maintenance of a urine output that permits adequate urinary lead excretion, and (3) control of seizures with anticonvulsants. Critical elevations in intracranial pressure may be signaled on examination by a progressive decline in level of consciousness, papilledema, cranial nerve dysfunction, abnormal pupillary responses, or focal neurologic deficits. Elevated intracranial pressure may be confirmed by neuroimaging or direct intracranial pressure measurement. Emergent treatment should include hyperosmolar agents (e.g., intravenous mannitol 0.25–1.0 g/kg as a 20–25% solution or hypertonic saline) as well as intubation and short-term hyperventilation initially targeted to a PaCO₂ of 30–35 mmHg [128, 129]. Because the pathophysiology of cerebral edema in lead encephalopathy involves altered permeability of the brain microvasculature, there is theoretical benefit to the use of glucocorticoids, such as dexamethasone. However, the evidence supporting their use is very limited. If seizures occur, benzodiazepines, such as diazepam or lorazepam, are the anticonvulsants of choice, with recourse to supplemental propofol, phenobarbital, or general anesthesia in recalcitrant cases. The use of phenothiazines for sedation or treatment of delirium should be avoided because they may lower the seizure threshold.

Lead is excreted predominantly through the kidney, and elimination is optimized when urine output is maintained at 1–2 mL/kg/h (Grade III recommendation). Patients with lead encephalopathy are often volume depleted due to vomiting or decreased oral intake, requiring intravenous fluid to achieve this goal. Fluid supplementation must be managed carefully to avoid volume overload and exacerbation of cerebral edema. In critically ill encephalopathic patients, optimization of fluid status may require invasive hemodynamic monitoring and intracranial pressure monitoring. In

patients without intravascular volume depletion, fluids should be minimized, and urine output should be augmented as needed with loop diuretics or by the secondary diuretic effects of mannitol administered for treatment of cerebral edema.

Transfusion of packed red blood cells may be of potential therapeutic benefit in the severely symptomatic patient with a hematocrit less than 30 and a blood lead concentration greater than 100 µg/dL (>4.8 µmol/L). The fraction of blood lead found in plasma (normally $<1\%$) increases at a supralinear rate in the presence of high blood lead concentrations or low hematocrits [10, 130]. Plasma lead has a greater capacity than erythrocyte-associated lead to cross endothelial barriers or cell membranes and partition into critical target organs, particularly the brain [131, 132]. A high blood lead concentration in the presence of severe anemia is of even greater toxicologic concern than the same level in the presence of a normal hematocrit. Transfusion of packed red blood cells in an anemic, encephalopathic patient with a high blood lead level may be of benefit by lowering the plasma fraction of lead in the blood. Anecdotal experience suggests that this intervention is of clinical value, but it has not undergone systematic study.

Before the more widespread use of chelating agents in the 1960s, adults with acute lead colic frequently were treated with intravenous injection of calcium salts, which was observed to provide rapid, dramatic relief from the abdominal pain. Hunter [133] noted, "In severe cases, it is possible, by the slow intravenous injection of 15 mL of a 20% solution of calcium gluconate, or of 10 mL of a 5% solution of calcium chloride, to relieve the pain by the time the injection is over." Hamilton and Hardy [58] commented, "So dramatic is the effect of calcium that there is no need to use morphine or atropine." Soon after the introduction of the chelating agent calcium EDTA in the early 1950s, Belknap and Perry [134] described the sequential use of calcium gluconate and calcium edetate in patients with acute lead colic, a regimen they believe combined the rapid pain relief of the former with the lead-mobilizing effect of the latter. These investigators noted the following:

Intravenous treatment with edathamil calcium disodium ($\text{CaNa}_2\text{-EDTA}$) does not give the prompt relief of lead colic which we expect within one-half hour with intravenously administered calcium gluconate. Therefore, a combination of intravenously administered calcium gluconate in alternate doses with intravenously administered edathamil calcium disodium is calculated to give immediate pain relief, combined with a sharp reduction of circulating, and therefore potentially dangerous lead.

By the mid-1960s, chelation alone supplanted the use of calcium salts in the treatment of the progressively rarer adult patient with acute lead colic. Aside from the observations of Belknap and Perry [134], there seems to be scant discussion in the literature regarding clinical experience with calcium salts or opioids as adjuncts to chelation in the treatment of this condition. Slow intravenous administration of calcium gluconate (e.g., 30 mL of a 10% solution over 20 min in an adult) could be considered as an adjunctive measure in patients with lead colic that does not promptly respond to continuous infusion of calcium EDTA.

Chelation

Several pharmaceuticals, known as *chelating agents* or *chelators*, are available for the treatment of lead intoxication. The principal agents are sodium calcium edetate (edetate calcium disodium or calcium EDTA) and the three dimercapto compounds – dimercaprol (dimercaptopropanol, British antilewisite), succimer (*meso* 2,3-dimercaptosuccinic acid, DMSA [Chemet]), and unithiol (dimercaptopropanesulfonic acid, DMPS [Dimaval]). Calcium EDTA and, in the case of the dimercapto agents, either the parent compound or the biotransformation products are thought to form relatively stable complexes with the lead atoms in vivo, enhancing lead mobilization and diminishing interaction with cellular proteins. Administration of each of the chelating agents results in reductions in blood lead concentrations and large increases in urinary lead excretion. There are no randomized clinical trials, however, that establish the ability of chelation to improve clinical outcome in lead-poisoned patients. There was no

apparent benefit of chelation on survival in one of the few controlled animal studies that examined chelation treatment of acute high-dose lead poisoning [135]. A randomized, placebo-controlled, double-blind study of chelation with succimer in children with blood lead concentrations of 25–44 $\mu\text{g/dL}$ (1.2–2.1 $\mu\text{mol/L}$) found no benefit in neuropsychologic outcome or long-term blood lead reduction [136]. For children with lead encephalopathy, the benefit of chelation has been suggested by the sharp decline in the case mortality rate since this treatment was introduced. In the 1940s, before the availability of chelating drugs, the case mortality rate for severe pediatric lead encephalopathy was approximately 65%, but it decreased to less than 5% among similar cases treated with chelation in the 1960s [55, 137, 138]. In nonencephalopathic patients with high blood lead concentrations, chelation has been advocated as a means to decrease blood lead concentration rapidly and avert possible progression to encephalopathy, a condition that potentially can result in death or permanent neurologic sequelae [49].

Various chelation regimens have been proposed over the years (Table 1). Dimercaprol was investigated as a chelating agent for lead intoxication soon after its introduction as an arsenic antidote in the mid-1940s. In contrast to its beneficial effect in acute arsenic poisoning, dimercaprol did not prolong survival in animals challenged with lethal doses of lead acetate, despite increasing urinary lead excretion [139, 140]. In these animal experiments, dimercaprol actually increased the toxicity of lead. In early human case series, dimercaprol was thought to be of possible value in severe pediatric lead encephalopathy [137], but it was considered to be less useful in adult cases, particularly patients with lead colic [141, 142]. Calcium EDTA, introduced in the early 1950s, generated far more enthusiasm for its perceived therapeutic benefit [16, 143]. Calcium EDTA replaced dimercaprol as a single agent in the treatment of lead intoxication after several pediatric case series associated it with better neurologic outcome among survivors and a higher therapeutic index [51, 144].

In a small randomized clinical trial conducted in the 1960s, Chisolm [138] observed that a

two-drug regimen consisting of dimercaprol and calcium EDTA resulted in a more rapid decline in blood lead concentration and greater urinary lead excretion than those achieved with calcium EDTA alone. By administering the highest tolerable dose of two distinct types of agents, it was thought that the overall delivery of chelating moieties could be maximized. It also was suggested that the relatively higher lipophilicity of dimercaprol mobilized lead from intracellular sites and then shifted it extracellularly, where a more stable lead-EDTA chelate could be formed [145]. In a common two-drug regimen developed for pediatric lead encephalopathy [146], treatment is begun with a priming dose of dimercaprol, 75 mg/m^2 intramuscularly, which is repeated every 4 h for a total daily dose of 450 $\text{mg/m}^2/\text{day}$. Four hours after the initial dimercaprol dose, calcium EDTA, 1500 $\text{mg/m}^2/\text{day}$, is begun by slow, continuous intravenous infusion. Calcium EDTA (Calcium Disodium Versenate) is supplied in 5-mL ampoules (200 mg/mL), which should be diluted to 2–4 mg/mL in saline or 5% dextrose for intravenous infusion. Although intramuscular injection of undiluted calcium EDTA (combined with lidocaine for local analgesia) sometimes has been advocated to minimize fluid load in encephalopathic patients with cerebral edema, the small amount of fluid required for intravenous infusion carries minimal risk and ensures efficient systemic delivery. The combined regimen of dimercaprol and calcium EDTA is continued for 5 days, although in some cases dimercaprol is discontinued after 3 days if the blood lead concentration has decreased to less than 50 $\mu\text{g/dL}$ (<2.4 $\mu\text{mol/L}$). Other two-drug regimens have used a dimercaprol dose of 4 mg/kg intramuscularly every 4 h (slightly higher than 5 mg/m^2 in an average-size child) [138]. Alternative calcium EDTA doses have included 1000 $\text{mg/m}^2/\text{day}$ (approximately 40 mg/kg/day in an average-size child) [147] or 50 mg/kg/day [148].

Dimercaprol is supplied dissolved in peanut oil in 3-mL ampoules (100 mg/mL) for deep intramuscular injection. Dimercaprol is associated with a high incidence of adverse side effects, including nausea and vomiting, hypertension, prolongation of the partial thromboplastin time, fever (particularly in children), and pain at the

Table 1 Venous blood lead level after an initial course of chelation as a percentage of pre-course value (ECP)

Study	Drug	Dose regimen	Drug administration method	Number of treatment courses	Mean pre-course VBLL ($\mu\text{g}/\text{dl}$)	ECP

injection site. Sterile or pyogenic abscesses at the injection sites also may occur. Because it is supplied in a peanut oil vehicle, it should not be used in patients who have an allergy to peanuts. Although combined therapy with dimercaprol and calcium EDTA accelerated the decline in blood lead concentration, there is little evidence that the addition of dimercaprol to calcium EDTA monotherapy measurably improves clinical outcome [86, 138]. In 1992, a retrospective study of the treatment of hospitalized, nonencephalopathic children with blood lead concentrations of 50–60 µg/dL (2.4–2.9 µmol/L) found that treatment with calcium EDTA alone produced a greater short-term reduction in blood lead than did combined treatment with dimercaprol and calcium EDTA [149]. Patients not treated with dimercaprol displayed fewer adverse side effects. Because of dimercaprol's side-effect profile and the limited nature of the data supporting its added value, some clinicians omit it from chelation regimens of severely lead-poisoned patients, particularly adults. In encephalopathic adults with massively elevated blood lead concentrations (>400 µg/dL [>19.3 µmol/L]), treatment has been initiated with calcium EDTA alone without complications [59, 150, 151]. The dosage of calcium EDTA used in adults with lead encephalopathy or lead colic is usually 2–4 g/24 h, or approximately 30–50 mg/kg/day, administered as a continuous intravenous infusion. Although formal dose–response studies have not been conducted, limited evidence suggests that higher doses are not associated with substantive increases in urinary lead excretion [152].

Courses of treatment with calcium EDTA are limited to 5 consecutive days to diminish the risk of nephrotoxicity reported with prolonged high doses [153–155]. In patients with acute lead intoxication who receive chelation therapy soon after their lead exposure ends, the peak urinary lead excretion usually occurs within the first 2 days [51, 138, 152]. A report that an initial dose of calcium EDTA redistributed lead to the brain of rats [156] was not replicated in a more recent investigation conducted with sensitive measurement of a stable lead isotope tracer [157].

Based on clinical trials conducted in nonencephalopathic patients with blood lead concentrations less than 100 µg/dL (<4.8 µmol/L), oral succimer, a water-soluble analogue of dimercaprol, seems equivalent or slightly more effective than parenteral calcium EDTA in lowering blood lead concentrations [17, 158–160]. Oral succimer is nearly comparable to parenteral calcium EDTA in mobilizing lead into the urine [160, 161]. These clinical trials and other experimental studies and clinical reports reviewed in detail by Bradberry and Vale [23] have not established the overall clinical superiority of either drug in the treatment of lead poisoning. Accordingly, for many years succimer has been considered an acceptable alternative to calcium EDTA, or dimercaprol/calcium EDTA combination therapy, in nonencephalopathic lead-poisoned patients who are able to tolerate an oral medication.

Recent clinical experience with a large cohort of lead-poisoned children in rural Nigeria exposed to lead contaminated dust and soil as a consequence of artisanal gold mining of lead-laden ore established that oral succimer was pharmacologically effective in decreasing blood lead concentration in patients with lead encephalopathy [162]. In a subset of hospitalized children with a geometric mean pretreatment blood lead concentration of 106 µg/dL (5.1 µmol/L), the blood lead concentration had declined an average of 55% at the end of a 19 or 28 day in-patient course of oral succimer. Declines in blood lead of a similar magnitude have been observed in children in the United States chelated with either succimer or calcium EDTA ([162], Table 8).

There is some evidence that the chelating effect of succimer in humans requires *in vivo* biotransformation to form succimer-cysteine adducts [163, 164]. The possible impact of very high blood lead concentrations on this biotransformation is unknown. In a case report, oral succimer was added to a regimen that included calcium EDTA and dimercaprol for treatment of an encephalopathic child with a blood lead concentration of 550 µg/dL (26.6 µmol/L) [116]. In that case, blood lead concentrations rebounded upward when the parenteral chelators were stopped, even though succimer was continued. A

controlled retrospective study in nonencephalopathic pediatric patients with mean blood lead concentrations of 50–60 $\mu\text{g/dL}$ (2.4–2.9 $\mu\text{mol/L}$) found that two-drug therapy with succimer and calcium EDTA was equivalent to two-drug therapy with dimercaprol and calcium EDTA in lowering blood lead concentration but resulted in fewer adverse side effects [165]. A direct comparison of two-drug therapy with monotherapy was not conducted.

Succimer is supplied as 100 mg capsules (Chemet[®] in North America) or 200 mg capsules (Succicapital[®] in Europe) for oral administration. The small size of the 100 mg capsules reflects the drug's US Food and Drug Administration–approved indication as a treatment for lead poisoning in children. The medication is equally effective in adults, however. A commonly used treatment regimen consists of 10 mg/kg orally (in children, 350 mg/m²) every 8 h for 5 days, decreasing to every 12 h for the next 14 days [166]. Succimer generally is well tolerated, although adverse effects, including gastrointestinal distress, allergic skin rashes, mild reversible elevations in liver transaminases, and mild-to-moderate neutropenia, occasionally have been noted. A study conducted in primates found that oral treatment with succimer does not increase absorption of lead that may be present in the gastrointestinal tract [167]. Nonetheless, the whole bowel irrigation that is indicated in some cases of recent lead ingestion with radiographic signs of lead particles in the gastrointestinal tract (see earlier) prevents initiation of oral chelation until the decontamination process is completed. The clinical pharmacology of succimer is discussed in ► Chap. 165, “Succimer.”

The initial use of an oral medication may also be problematic in encephalopathic patients, who may have nausea, vomiting, or obtundation, or in patients with severe lead colic, in whom gastrointestinal motility often is compromised. However, in the recent pediatric lead poisoning epidemic in rural Nigeria mentioned above, 26 unintubated obtunded patients with lead encephalopathy were initially administered succimer via nasogastric tube in the resource-limited field hospital. Three of the patients died from severe lead

encephalopathy early in treatment; one developed pneumonia of uncertain etiology and recovered; the others tolerated the nasogastric administration without complication [162]. In fully resourced critical care settings, an unconscious encephalopathic patient would be intubated for airway protection prior to nasogastric administration of succimer or other medication. The sodium salt of succimer, sodium dimercaptosuccinate, has been used in the intravenous treatment of lead poisoning in the People's Republic of China, but at present this formulation is not available elsewhere. In a small study, intravenous succimer at a dose of 1–2 g/day was found to be equivalent to intravenous calcium EDTA in increasing urinary lead excretion in adults [23, 168, 169] (Grade I evidence).

Unithiol, another water-soluble analogue of dimercaprol, is similar to succimer in its capacity to decrease tissue levels of lead in experimental animals [170]. Treatment with oral unithiol has resulted in a decline in blood lead concentration and an increase in renal lead excretion in the relatively few reports of its use in the treatment of human lead intoxication [18, 171]. No published reports are available regarding the use of unithiol in the treatment of patients with lead encephalopathy or patients with extremely high blood lead concentrations (>150 $\mu\text{g/dL}$ [$>7.2 \mu\text{mol/L}$]). Unithiol is available in oral and parenteral formulations. It has been sold as a registered pharmaceutical in Germany and Russia for many years, but it only more recently became available in the United States for dispensation through compounding pharmacies [172]. Unithiol generally is well tolerated, although rare allergic cutaneous reactions and isolated cases of mild reversible transaminase elevation or leukopenia have been observed [173]. D-Penicillamine has been used for oral lead chelation but is inferior to succimer in lead mobilization [174] and is associated with a higher incidence of adverse effects [175–177]. The clinical pharmacology of these two agents is discussed in detail in their respective chapters.

The selection of a chelation regimen in a patient with symptomatic lead intoxication is influenced by the nature and severity of the clinical presentation. In patients with lead

encephalopathy or severe lead colic, intravenous calcium EDTA remains the current treatment of choice. As discussed earlier, some clinicians have advocated a combined regimen of dimercaprol and calcium EDTA, particularly in children. After 5 days, or possibly sooner if the patient is alert and able to tolerate an oral medication, the parenteral chelation agent may be replaced by an oral chelation agent, such as succimer or possibly unithiol if succimer is not available. Measurement of blood lead concentration immediately before initiation or alteration of any chelation regimen and repeat measurements 24–48 h later are indicated to confirm that blood lead levels are declining. Measurement of urinary lead during the first 24 h of chelation therapy may provide further assurance of substantive lead excretion, which can exceed several milligrams in the initial days of therapy [16, 19, 20, 22, 23]. If blood lead concentration increases after replacement of calcium EDTA with an oral chelator or if it remains greater than 100 µg/dL (>4.8 µmol/L), a second course of calcium EDTA is indicated. Each 5-day course of calcium EDTA should be separated, however, by a 2-day interval in which that drug is withheld. Further research is warranted to assess the clinical value of regimens that combine calcium EDTA with succimer or unithiol.

In adults who have symptomatic lead intoxication without evidence of encephalopathy or lead colic (usually at blood lead concentrations >60 – 80 µg/dL [>2.9 – 3.9 µmol/L]) and in children with blood lead concentrations greater than 45 µg/dL (>2.2 µmol/L) who likewise do not have encephalopathy or colic, chelation treatment may be initiated with oral succimer. Oral unithiol also may be appropriate in this setting. Because of limited experience regarding the use of succimer or unithiol as the sole chelating agent in patients with extremely high blood lead concentrations (>150 µg/dL [>7.2 µmol/L]), it is prudent to monitor the initial clinical progress and blood lead trend of such patients in an inpatient setting.

To avert potential progression to encephalopathy, which sometimes evolves abruptly after a symptom-free latent period [59], chelation is warranted for asymptomatic adults with blood

lead concentrations greater than 100 µg/dL (>4.8 µmol/L). Similarly, chelation has been recommended for all children with blood lead concentrations greater than 45 µg/dL (>2.2 µmol/L), even in the absence of symptoms [93, 148] (Grade III recommendation). Studies have observed that the urinary excretion of lead after succimer administration is influenced by at least two genetic polymorphisms [13]. Occasionally, some individuals who excrete large quantities of lead after calcium EDTA excrete considerably lesser amounts after succimer [19]. A small study of the pharmacokinetics of succimer found that clearance of the drug and its metabolites may be prolonged in lead-poisoned children relative to lead-poisoned adults [178], and another investigation observed that the half-life of succimer elimination was prolonged at elevated blood lead concentrations [179]. Although further study of these factors is necessary, the clinician should be alert to the possibility that an occasional patient may not respond to chelating agents with a substantial increase in urinary lead excretion or decline in blood lead concentration ($\geq 20\%$ by 48–96 h). Although genetic or medical factors in the patient may be responsible, the possibility of noncompliance, ongoing occult exposure, or retention of lead in the gastrointestinal tract or in a synovial cavity also should be considered.

After termination of lead exposure, the pattern of decline in blood lead concentration is approximated by a two-compartment model: a fast, initial decline reflecting clearance of lead in the soft tissues followed by a slow, second phase representing the major body burden of lead present in bone [180]. Chelating agents, which predominantly mobilize lead from the soft tissues, accelerate the initial rate of decline associated with the first compartment but exert a relatively modest impact on the second (skeletal) compartment. The ability of chelation to clear even the soft tissues of lead has limitations. In a study of juvenile primates, 77% of an injected lead isotope was retained in the body after 5 days of oral succimer, even though chelation was begun 15 min after the injection [181]. The amount of lead excreted in the urine during a course of

Fig. 1 Response of blood lead concentrations to brief courses of chelation therapy. Data were obtained in two patients. *Solid-line* segments show decrease in blood lead concentrations during and after therapy with calcium

disodium edetate (or dimercaprol and calcium disodium edetate), and *dashed-line* segments show trend in blood lead concentration without chelation therapy (From Moel et al. [182], with permission)

chelation, often on the order of 10 mg within 1 week in a symptomatic individual, is small relative to the hundreds of milligrams that may be present in the skeleton after chronic or recurrent high-dose exposure.

In patients with a pattern of chronic or acute-on-chronic, high-dose lead exposure, cessation of chelation typically is followed by an upward “rebound” in blood lead concentration over the next few weeks as lead in the skeleton reequilibrates with the circulation. In general, the first one or two courses of chelation have an appreciable and enduring capacity to reduce blood lead concentrations below the high values associated with major, overt symptoms. Because of postchelation rebound from bone lead stores, however, subsequent courses of chelation may have only a modest impact on the long-term pattern of decline in blood lead concentration (Fig. 1) [182]. The benefit of repeated courses of chelation in these settings has not been established [183]. A key component of successful clinical management is assurance that the patient is not discharged to an environment where hazardous lead exposure will continue and close collaboration with occupational or environmental public health agencies, social work services, outpatient case managers, or employers is important in this regard.

Prognosis

The long-term prognosis for complete recovery from severe lead intoxication in children is guarded. In a series of 425 children treated for lead intoxication published in 1966, Perlstein and Attala [49] observed neurologic sequelae in 168 cases (39%). Among a subset of 59 patients who survived lead encephalopathy, 54% were noted to have a persistent seizure disorder; 38% were described as having mental retardation (“generally of a profound type”); and 13% were said to have cerebral palsy, usually characterized by spastic hemiplegia. Although 18% were believed to have no sequelae, this and other early studies did not assess the long-term effects of childhood plumbism on subclinical neurocognitive or neurobehavioral outcome. More recent long-term prospective studies of asymptomatic children with mild-to-moderate elevations in lead exposure have found evidence of enduring subclinical deficits in cognitive function or educational performance [184–186].

The long-term outcome of adults with overt lead poisoning, including encephalopathy, has not been subject to formal prospective study, but in general these patients experience considerable improvement in symptoms after removal from

exposure and decline in blood lead concentration. Most patients experience complete recovery from gastrointestinal symptoms and anemia. Peripheral neuropathy also improves, although patients who sustained severe insults may have residual deficits. The prospect for recovery of clinical neurocognitive and neurobehavioral function is favorable, although the rate of improvement may lag behind the decline in blood lead concentration. Reduction in brain lead occurs more slowly than reduction in blood lead, particularly during chelation [28, 181]. A program of physical therapy and cognitive rehabilitation may foster improvement in neurologic function. Depending on the severity of intoxication, complete functional recovery in some patients may require 1 year or more, and occasional patients, particularly the elderly, may have persistent cognitive deficits. A study that used noninvasive X-ray fluorescence to measure lead in bone in former organolead workers found an association between past adult lead exposure and longitudinal decline in cognitive function [187].

Special Populations

Patients with Renal Insufficiency

Lead excretion in humans occurs predominantly via the kidney. In patients with lead poisoning, chelating agents initially can increase daily urinary lead excretion by 10-fold to 50-fold [17, 18, 20–23]. The effect of chelation on lead elimination in the presence of renal failure has been best characterized for calcium EDTA. In patients with moderate renal insufficiency but preserved urine output, calcium EDTA results in large increases in urinary lead excretion but at a slower rate than what occurs in patients with normal renal function [188, 189]. When treating these patients for symptomatic lead intoxication, it is advisable to decrease the administered dose of calcium EDTA by half (e.g., 1 g/24 h in an adult instead of 2 g/24 h) (Grade III recommendation).

A few case reports suggest that calcium EDTA can be combined with extracorporeal

techniques to increase lead elimination in patients with severe renal failure. A patient with chronic lead poisoning and end-stage renal failure received calcium EDTA, 500 mg intravenously, before peritoneal dialysis. The amount of lead removed in the dialysate increased 4.5-fold, resulting in elimination of 16.8 mg of lead in 20 h [190]. In another patient with chronic renal failure, calcium EDTA, 1.0 g intravenously, increased the amount of lead removed by peritoneal dialysis from a baseline of 16 µg/day to 1932 µg over 4 days [191]. Kessler and colleagues [192] used calcium EDTA, 1.0 g intravenously, 1 h before hemofiltration to increase lead removal in patients with end-stage renal failure. In like manner, administration of 1 g of calcium edetate in 250 cc normal saline intravenously over 1 h followed immediately by 4 h of hemodialysis using a high flux dialysis membrane, such as the F160, was followed by an accelerated decline in blood lead concentration [193].

Because effective lead mobilization by succimer may require biotransformation in the kidney to form a 1:2 dimercaptosuccinic acid–cysteine adduct [164, 179], there is reason to doubt its potential ability to increase lead elimination in patients with end-stage renal failure. In limited unpublished reports, succimer did not seem to increase lead clearance by hemodialysis [166].

Pregnant Patients

Lead undergoes transplacental transport, and at low-to-moderate blood lead concentrations, umbilical cord blood lead levels at delivery are approximately 85–90% of the maternal blood lead [194]. Factors that elevate the plasma fraction of maternal blood lead (e.g., high blood lead concentrations, anemia, or high maternal bone lead burden) [195] are likely to increase fetal lead exposure. High-dose lead exposure during pregnancy has been associated with an increased risk of spontaneous abortion and stillbirth. Lead has been used illicitly as an abortifacient [196], and

studies of reproductive outcome among women with relatively high occupational lead exposure in the late nineteenth and early twentieth centuries noted a high incidence of miscarriage and still-birth [197]. Contemporary epidemiologic studies generally have not detected an association between maternal blood lead concentrations less than 30 µg/dL (<1.4 µmol/L) and an increased risk of spontaneous abortion, although a nested case-control study found an odds ratio for spontaneous abortion of 1.8 (95% confidence interval 1.1–3.1) for every 5 µg/dL (0.24 µmol/L) increase in maternal blood lead over an approximate range of 5–20 µg/dL (0.24–1.0 µmol/L) [198].

Epidemiologic studies have yielded mixed results regarding a possible link between low-level lead exposure and preterm delivery or low birth weight [199–203]. Recently, two large studies of maternal–infant pairs in which the prenatal blood lead concentration was less than 10 µg/dL (0.5 µmol/L) found an inverse association between blood lead and birth weight [202, 203]. Most long-term prospective studies have found postnatal but not prenatal low-level lead exposure to be associated with subclinical decrements in cognitive function [102, 204]. However, long-term prospective studies in Yugoslavia [205] and Mexico City [206] have observed an enduring impact of prenatal lead exposure on the cognitive skills of school age children. Although high-dose lead exposure has been teratogenic in animal studies, there is no established link between in utero lead exposure and structural deformities in humans [94, 204].

Animal studies found that chelating agents may reduce the fetotoxic and teratogenic effects of lead. When administered to pregnant rats simultaneously with lead, equimolar doses of calcium EDTA greatly diminished lead-induced resorptions and malformations [207]. Although the calcium EDTA transiently increased transplacental lead transfer during a 64-min infusion, maternal lead clearance was enhanced, and fetal lead content was reduced greatly at 24 and 48 h after injection [208]. Oral succimer administered to lead-exposed pregnant rats prevented lead-induced decrements in the body weight of the

offspring assessed at the time of weaning and at 13 weeks of age [209]. Despite these beneficial effects, the use of chelating agents during pregnancy is tempered by the findings in animal studies that calcium EDTA was teratogenic at therapeutic doses [210] and that succimer was fetotoxic when administered at three times the standard therapeutic dose [211]. These findings may have been mediated by impacts on trace mineral metabolism, particularly zinc in the case of calcium EDTA [210] and copper in the case of succimer [212, 213]. Judicious trace mineral supplementation conceivably might mitigate adverse effects on the fetus in the event of chelation for maternal lead poisoning. Reports of lead during pregnancy are sparse. In two cases, calcium EDTA treatment of lead poisoning during the third trimester was followed soon by delivery of a normal infant [214, 215]. Although these cases and four out of five additional reports all described in a recent review noted similar seemingly favorable outcomes [216], the therapeutic impact of chelation on reproductive outcome in this setting remains uncertain. The same applies to assessment of rare instances of exchange transfusion followed by chelation undertaken for markedly elevated blood lead concentrations in the neonatal period [217–219].

Common Misconceptions About Lead Poisoning

1. The clinical presentation of *lead encephalopathy* sometimes is mistaken for a central nervous system infection or mass lesion.
2. The clinical presentation of *lead colic* sometimes is mistaken for appendicitis, pelvic inflammatory disease, biliary colic, renal colic, intestinal obstruction, pancreatitis, or peptic ulcer disease. Although useful, an occupational and environmental history often is omitted.
3. Basophilic stippling of erythrocytes, gastrointestinal radiopacities, gingival lead

(continued)

lines, and radiographic skeletal lead lines (in children) occasionally provide useful clues, but the absence of these insensitive findings should not exclude the diagnosis.

4. An elevation in blood lead concentration ultimately should confirm the diagnosis, but treatment for clinically suspected severe lead intoxication should not be withheld pending a laboratory delay of one or more days.

Key Points in Lead Poisoning

1. Lead encephalopathy should be suspected in patients with delirium or seizures and laboratory evidence of anemia.
2. Lead colic should be suspected in patients with abdominal pain, constipation, and anemia.
3. Blood lead concentration usually is $>100 \mu\text{g/dL}$ ($>4.8 \mu\text{mol/L}$) in adults with lead encephalopathy ($>70 \mu\text{g/dL}$ [$>3.4 \mu\text{mol/L}$] in children). In lead colic, blood lead concentration usually is $>80 \mu\text{g/dL}$ ($>3.9 \mu\text{mol/L}$).
4. Lead encephalopathy and lead colic may occur independently of each other, but other antecedent multisystemic findings almost always are present.
5. Effective treatment requires attention to decontamination, supportive care, and use of specific chelating agents. Intensive supportive care for lead encephalopathy may require hyperosmolar agents (e.g., mannitol or hypertonic saline), hyperventilation, corticosteroids for cerebral edema, and anti-convulsants for seizures.

Mercury is a naturally occurring metal that exists in several physical and chemical forms. *Inorganic mercury* refers to compounds formed after the combining of mercury with elements such as chlorine, sulfur, or oxygen. After combining with carbon by covalent linkage, the compounds formed are called *organic mercury compounds* or *organomercurials*. The most common forms of mercury in the environment are elemental mercury, mercuric sulfide (cinnabar ore, from which elemental mercury is refined by heating), mercuric chloride, and the organic mercury compound methylmercury. In the environment, methylmercury is produced by the methylation of inorganic mercury by microorganisms. This form of mercury may enter and accumulate in the aquatic food chain [1]. Major methylmercury poisonings occurred in Minamata Bay, Japan, in the 1950s after the consumption of contaminated seafood following severe industrial mercury discharge into the bay. Another mass tragedy occurred in Iraq in 1971–1972 after the consumption of bread contaminated with methylmercury used as a fungicide on seed grain [2].

All forms of mercury have specific toxicity profiles to consider on exposure. The routes of exposure, toxicokinetics, target organs, and treatments differ to a great extent [3]. Acute toxicity usually is seen after inhalational exposure to elemental mercury vapors and ingestion of inorganic mercury compounds. Exposure to organic mercury most commonly occurs as a result of ingestion of seafood or other contaminated food products [4].

Exposures to elemental mercury without appreciable clinical relevance are the following. A frequently occurring exposure, especially in children, is the ingestion of small amounts of elemental mercury from a broken oral thermometer. After ingestion, elemental mercury is absorbed poorly from a normally functioning gastrointestinal tract. Because of this limited absorption and the small volume typically ingested, these elemental mercury exposures are considered nontoxic. If gastrointestinal function or anatomy is abnormal, however, elemental mercury may be absorbed into the blood or extravasate into the peritoneal space. The same is true of elemental

mercury in the rectum from a broken thermometer. Dermal exposure to elemental mercury vapor or liquid poses a minor occupational hazard compared with inhalational exposure because skin absorption is minimal [5]. Although there has been some concern about whether mercury vapors released from dental amalgam fillings pose health risks, there is no scientific evidence of toxic effects from these exposures [6, 7].

Mercury Compounds and Sources

Elemental Mercury

Synonyms for elemental mercury are metallic mercury (Hg^0), quicksilver, liquid silver, and hydrargyrum. Elemental mercury is a silvery, shining liquid at room temperature. It is a heavy metal with a high vapor pressure of 0.002 mmHg at 25 °C. Consequently, at room temperature, some mercury evaporates. These vapors are colorless and odorless; vaporization increases significantly when mercury is heated. After accidental spills, metallic mercury and its vapors are difficult to remove. Especially in enclosed rooms, significant concentrations may be reached. If decontamination is not carried out properly, this can result in prolonged exposure. Most intoxications arise from occupational exposures, mainly in mining and extracting processes, in industrial plants as chlor-alkali plants, in dental amalgam preparation, and in the manufacture and repair of instruments such as mercury thermometers, barometers, sphygmomanometers, batteries, electrical switches, and (compact) fluorescent lamp bulbs. Part of the mercury vapor originally inside a bulb converts to mercuric oxide. Elemental and inorganic mercury can be present in herbal preparations and used in religious and spiritual remedies.

Inorganic Mercury Salts

Synonyms for and examples of inorganic mercury salts are mercurous ion (Hg^+), mercuric ion (Hg^{2+}), mercurous chloride (HgCl , calomel), mercuric chloride (HgCl_2 , corrosive sublimate), and mercuric

oxide (HgO). Inorganic mercury exists primarily as a salt of monovalent (mercurous) or divalent (mercuric) forms. Concentrations of 1–5% of inorganic mercuric salts, such as mercuric chloride, already cause irritation, vesiculation, and corrosion of the skin. Corrosive damage will also occur after ingestion [8]. Mercuric chloride is a common salt. Inorganic mercury compounds have had many uses (e.g., as antibacterials, topical antiseptics, components of skin-lightening products, paints, tattoo dyes [red mercuric sulfide], diuretics, and cathartics). Currently, mercuric oxide still is used in batteries.

Organic Mercury

Organic mercury exists in three major forms: aryl, short-chain alkyl, and long-chain alkyl compounds. Methylmercury, a short-chain alkyl compound, is the predominant form of organic mercury found in the environment. In the short-chain alkyl compounds, there is a stable carbon–mercury bond. In the long-chain alkyl and aryl compounds, such as phenylmercury salts, the carbon–mercury bond is less stable, and the toxicity of these compounds may be due to the divalent mercury released after the carbon–mercury bond has been ruptured [2]. Organic mercury compounds have been used as biocides, as fungicides, as pesticides, as seed dressings, as antiseptics, as medicinal preservatives (thimerosal), and in paints.

Toxicokinetics

Elemental Mercury

The most important route of exposure is inhalation of mercury vapors. After inhalation, the lipid-soluble vapor rapidly diffuses across alveolar membranes, enters the blood, and partitions between plasma and red blood cells. Because of its high lipophilicity, mercury vapors are distributed throughout the body, including the central nervous system and fetus, if present. After absorption and distribution, most of the elemental mercury is oxidized intracellularly to inorganic

mercurous ions (and subsequently to mercuric ions) through the catalase–hydrogen peroxidase pathway. Mercuric mercury has a lower lipophilicity than unoxidized elemental mercury, which causes retention and accumulation of mercuric mercury in the brain, probably because of its presence as an insoluble selenium compound [9]. The further pattern of distribution changes toward that seen with inorganic mercury compounds, with accumulation primarily in the kidneys [2]. The overall retention of inhaled mercury vapor in human tissues is approximately 70–80% [10]. Elimination of elemental mercury occurs through expired air, urine, and feces [11]. Approximately 10% of an absorbed dose is exhaled in the first few days after exposure [12]. Urine and feces are the main excretory routes of mercury. In the first few days after acute exposure to high levels of mercury vapor, a large fraction of mercury can be found in the urine. Fecal excretion accounting for 50% of the total elimination was dominant after the first week [10, 11, 13]. In blood, there is an initial half-life of mercury of 2–16 days, followed by a half-life comparable to that observed in the kidneys of more than 1 month [10, 13]. The whole-body half-life of elemental mercury is about 60 days (range 35–90 days) [2].

Inorganic Mercury Salts

Approximately 10% of ingested mercuric chloride is absorbed. Disruption of the gastrointestinal mucosa may enhance mercury absorption. The monovalent mercurous salts are less soluble, and absorption is thought to depend on their oxidation to the divalent form [14]. Some mercuric compounds (e.g., HgS, HgSe) have such low solubility that they are regarded as nontoxic [15]. Cutaneous absorption of inorganic mercurials is possible, depending on the solubility of the vehicle. Although the mercuric ion's lipid solubility is low, with consequent poor penetration of the blood–brain barrier, chronic exposure, slow elimination, and the presence of a small amount of unoxidized elemental mercury (after reduction of inorganic mercuric ions) gradually result in accumulation of mercuric ions in the cerebellar and

cerebral cortices of the brain [16]. Mercuric ions do not readily cross the placenta [17]. In plasma, mercury is bound to protein. Most of the absorbed dose is accumulated in the kidneys [18]. Excretion of the circulating mercuric ion is mainly via the feces and urine. Elimination occurs by tubular secretion into the urine and by exfoliation of renal tubular cells [19]. Because renal excretion is inefficient, however, the mercury continues to accumulate in the kidney. Inorganic mercury can be secreted into bile. Small amounts of mercuric ions are reduced to elemental mercury vapor by reductase enzymes and oxygen dismutase and exhaled. The half-life of inorganic mercury is 30–60 days, with an average of approximately 40 days [2]. However, as for the half-life of inorganic mercury in the brain, current results from animal studies, human case studies including autopsy findings, and a few modeling studies indicate a half-life of several years to several decades [20].

Organic Mercury

Most organic mercury compounds are absorbed readily after ingestion. Gastrointestinal absorption of methylmercury (a short-chain alkyl compound) is about 90%. The absorption of aryl and long-chain alkyl compounds is less, but greater than 50% has been reported [17]. Dermal and inhalational absorption occur, although the extent is not known exactly. The exception is phenylmercury, which is not well absorbed after ingestion or dermal contact. After absorption, intracellular cleavage of the labile carbon–mercury bond of the aryl and long-chain organic mercurials causes rapid conversion to inorganic forms, resulting in kinetics and toxicity similar to those in inorganic mercury [11]. The short-chain alkyl mercurials are stable, and only a minor part is converted to inorganic forms. Because of their high lipophilicity, these short-chain alkyl compounds rapidly distribute throughout the body, with penetration of the blood–brain and placental barriers [11]. The brain-to-blood concentration ratio after completion of the initial distribution of methylmercury is about 10:1 [2]. Over the course of years,

conversion of methylmercury to inorganic mercury in the brain has been reported [21]. Accumulation of methylmercury in red blood cells results in a large red blood cell-to-plasma ratio (10:1) [17]. Accumulation of methylmercury is mainly in the kidneys and liver and to a lesser extent in brain tissues (although toxicity is expressed mostly in the brain) and hair [22]. Slow conversion of methylmercury to inorganic mercury also takes place in the kidneys. Elimination of methylmercury is predominantly fecal. Methylmercury binds to reduced glutathione and is secreted in bile [23]. The methylmercury–glutathione complex is degraded to cysteine complexes that are subject to reabsorption. The *N*-acetyl-homocysteine-methylmercury metabolite undergoes enterohepatic recirculation [11]. In the intestinal tract, a fraction of the methylmercury is converted to inorganic mercury and excreted in the feces [11]. The whole-body half-life of methylmercury is about 70 days [11, 24]. The half-life in blood is approximately 44 days [11, 24]. After the intravenous administration of methylmercury in volunteers, however, the half-lives were 44 days for the blood and whole body [24].

Pathophysiology of Toxic Effects

Elemental Mercury

Damage to the airways by elemental mercury vapor may be by direct-contact effects or may be indirect due to binding to sulfhydryl groups of enzymes and proteins. The vapor may cause an exudative alveolar and interstitial edema, with desquamation of the bronchiolar epithelium. The ensuing partial obstruction may result in alveolar dilation and the complications discussed subsequently in the section on “[Clinical Presentation](#)” [25]. After absorption and distribution, elemental mercury vapor is subject to oxidation (to mercuric ions) by the catalase–hydrogen peroxidase pathway. The oxidation process depends on the amounts of catalase and hydrogen peroxide in the cell, and inhibitors of catalase or competitive substrates can slow down the oxidation [2]. Mercuric cation can be reduced to elemental mercury

by processes involving reductase enzymes and oxygen dismutase [2]. At steady state, the oxidation–reduction reaction of absorbed elemental mercury favors the mercuric cation, however [26]. This conversion to inorganic mercury is responsible for mercury toxicity. Differences in the patterns of toxicity between inhaled mercury vapors and inorganic compounds are attributed to differences in lipophilicity and primary distribution and to specific characteristics of the inorganic compounds involved (e.g., corrosive features).

Inorganic Mercury Salts

The major mechanism of biologic activity of inorganic mercury *in vivo* is its reaction with sulfhydryl groups [2]. The covalent binding to sulfur replaces the hydrogen ion in the sulfhydryl group. This is an almost instantaneous reaction, causing a high-affinity binding of the divalent mercuric ion to thiol-containing molecules as proteins, cysteine, and glutathione [2]. Binding also occurs with phosphoryl, carboxyl, and amide groups [2]. Because of the binding to glutathione, inorganic mercury is secreted from liver cells into bile [2, 11]. The accumulation of the divalent cation in the kidneys induces the thiol-containing protein metallothionein [27]. This protein may play an important role in detoxification by forming a nontoxic Hg^{2+} -metallothionein compound. The divalent mercury cation also can give rise to oxidant free radicals that attack not only proteins but also DNA [2]. Through alterations in intracellular thiol status, mercury can promote oxidative stress, lipid peroxidation, and mitochondrial dysfunction. Widespread dysfunction of enzymes, transport mechanisms, membranes, and structural proteins results, leading to multiple organ dysfunction. Mercuric ions may directly injure the epithelial cells of the proximal renal tubules, causing renal tubular necrosis [28]. After the ingestion of corrosive mercuric salts, renal hypoperfusion due to shock also may cause renal tubular necrosis. An immune mechanism is attributed to the development of membranous glomerulonephritis. Type IV hypersensitivity reactions, which develop over 21–28

days after the exposure to mercury, underlie the formation of granulomas [29]. Granulomatous interstitial nephritis [29], granulomas forming after intravenous injection, and cutaneous mercury granulomas have resulted. Also, an idiosyncratic hypersensitivity reaction is often stated as the underlying pathophysiologic etiology for acrodynia, or “pink disease,” in children exposed to inorganic mercury. However, there seems to be a highly variable individual susceptibility as the syndrome develops in only a small proportion of those who are exposed and almost exclusively in small children [30]. There likely is a genetic component; two genetic polymorphisms associated with increased sensitivity to mercury have been identified [31].

The neuropathologic changes with elemental or inorganic mercury poisoning are different from the changes seen with organic mercury poisoning. Autopsy findings in patients who died after exposure to elemental mercury vapor reveal a well-preserved neuronal architecture, with the exception of decreased numbers of Purkinje and granular cells in the cerebellum [32] and prominent ischemic changes in the cerebellum in one patient and recent infarcts in the occipital lobe and the putamen in another [16].

Organic Mercury

The biochemistry of the methylmercury cation (CH_3Hg^+), the prototype of organic mercury poisoning, is similar to the inorganic cation. There also is a high affinity for sulfhydryl groups. Methylmercury does not induce metallothionein [2]. In high doses, methylmercury can cause severe damage to the adult brain and the developing brain. Methylmercury is toxic to the cerebral and cerebellar cortex, causing neuronal loss and reactive proliferation of the glial cells, microcavitation, vascular congestion, petechial hemorrhage, and edema [16]. The visual cortex (calcarine cortex), the auditory center in the temporal cortex, the cortical motor and sensory centers, and the cerebellar cortex are especially affected. In the fetal brain and developing brain, damage is diffuse because neuronal cell division and migration are

inhibited by blockage of the assembly process of microtubules in the neuronal cell [2]. As the experience in Minamata Bay dramatically illustrates, children can experience severe brain damage from prenatal exposure, even when the mother is much less affected [33].

Clinical Presentation

Elemental Mercury

After acute inhalation of vaporized elemental mercury, within hours of exposure, cough, chills, fever, headache, and shortness of breath can occur (mercury fume fever) [34, 35]. In addition, metallic taste; gastrointestinal complaints of nausea, vomiting, and diarrhea; salivation; excessive sweating; weakness; and visual disturbances can occur. Immune thrombocytopenia has been described in the acute phase [36]. At high concentrations, major pulmonary manifestations may develop, including necrotizing bronchitis, bronchiolitis, and pneumonitis, which can progress to pulmonary edema, respiratory failure, and death [37, 38]. Complications include multiple pneumothoraces, pneumomediastinum, and subcutaneous emphysema. Survivors of severe pulmonary manifestations may develop pulmonary fibrosis, granuloma formation, and residual restrictive pulmonary disease [39]. Children may be particularly susceptible to the pulmonary toxicity of mercury vapors [40].

The oxidation of elemental mercury to mercuric ions leads to features of inorganic mercury poisoning (described in the next section), characterized by renal toxicity, gingivostomatitis, and neurologic symptoms. Long-term, low-level exposure affects the neurologic system, with intention tremor and erethism (a condition characterized by increased irritability, excitability, anxiety, and shyness) as prominent features [41].

There are several case reports of other routes of exposure to elemental mercury. Aspiration of metallic mercury into the tracheobronchial tree has resulted in endobronchial hemorrhage and death [42]. Aspiration usually does not lead to acute or chronic mercury poisoning. Intravenous

injection of mercury can cause not only acute pulmonary embolus with respiratory failure but also pulmonary and systemic microembolisms. After oxidation to the mercuric cation, systemic inorganic mercury poisoning may occur. Subcutaneous injections or wounds contaminated with metallic mercury may cause local abscesses or granuloma formations. Systemic effects, including pulmonary embolization, have been reported but are unusual [43].

Inorganic Mercury Salts

After acute ingestion of mercury salts, the immediate features observed are related to the direct caustic effects of these salts, with mercuric ions being more toxic than mercurous ions [11]. After ingestion of mercuric chloride, effects can vary from severe irritation of the gastrointestinal tract to ulceration, necrosis, perforation, and acute hemorrhage, subsequently followed by hypovolemia, shock, electrolyte disturbances, and acute renal tubular necrosis with renal failure [8, 11, 44]. Immediately after ingestion, grayish discoloration of mucous membranes, metallic taste, nausea, vomiting, diarrhea, and severe abdominal pain occur. With the disruption of the gastrointestinal mucosa, mercury absorption can be extensive, and the direct toxicity of the mercuric cation on the proximal tubules further increases renal toxicity [8, 44]. Deterioration of renal function starts within hours after exposure.

If the patient survives these acute initial effects, systemic toxicity develops, as also is observed in subacute or chronic poisoning. Systemic toxicity includes renal dysfunction, gastrointestinal symptoms, neurologic toxicity, and cutaneous symptoms [26]. Chronic inorganic mercury poisoning also occurs after prolonged inhalation of elemental mercury vapor (owing to oxidation of elemental mercury) or after the *in vivo* dissociation of carbon–sulfur bonds of organic mercurial compounds, especially the aryl and long-chain alkyl mercurials [11]. The primary target organ is the kidney, with proximal tubular dysfunction. This dysfunction can range from asymptomatic, reversible proteinuria to tubular necrosis and

anuria [28, 29]. An immune glomerulonephritis may develop, which can lead to a full-blown nephrotic syndrome. Several cases of minimal change disease resulting in nephrotic syndrome have been published [45, 46]. Interstitial granulomatous nephritis has been described [29]. Oral symptoms of mercury intoxication include a metallic taste and burning sensation in the mouth, a blue lining of the gums, loose dentition, gingivitis, stomatitis, hypersalivation, and nausea [47]. Neurologic toxicity is expressed by tremor and syndromes such as neurasthenia and erethism, which include headache, irritability, excitability, delirium, anxiety, shyness, emotional lability, depression, loss of concentration and memory, fatigue, weakness, anorexia, and insomnia [41, 47]. Other neurologic manifestations include a mixed sensorimotor peripheral neuropathy, ataxia, constriction of visual fields, reduced color vision, and anosmia [41, 48].

As noted above, acrodynia (painful extremities) has been described primarily in children exposed to inorganic mercury. This is characterized by a pink maculopapular skin rash, particularly on the hands and feet, and hyperkeratotic induration also of the hands, feet, and face. In addition, excessive sweating, tachycardia, hypertension, photophobia, and neurologic symptoms, as mentioned previously, can occur [49]. Cutaneous manifestations of mercury toxicity may be a systemically induced allergic contact dermatitis, toxic contact dermatitis, or the formation of cutaneous granulomas, usually after injection of mercury [50].

Organic Mercury

Features of poisoning by long-chain alkyl and aryl organic compounds have some similarities to inorganic mercury toxicity but tend to be more subacute or chronic. Central nervous system toxicity is the hallmark of the short-chain alkyl compounds, particularly methylmercury. Clinical effects can be delayed for days to months after ingestion, depending on the amount ingested and the rate of enzymatic dysfunction. Neurologic effects start with paresthesias (facial and distal extremities) and headache and progress to ataxia,

dysarthria, visual field constriction, blindness, hearing disturbances, deafness, tremors, movement disorders, psychomotor retardation, and dementia. In severe cases, death ensues [1, 41]. Dimethylmercury poisoning has been reported in only a few cases of human poisoning, each proving fatal [51–53]. In a case of accidental dimethylmercury poisoning, a chemist spilled several drops onto a gloved hand. After cleaning up the spill, she removed her gloves. However, she developed delayed but ultimately fatal neurotoxic effects [53]. After ingestion of ethylmercury, gastrointestinal symptoms such as nausea, vomiting, abdominal pain, and diarrhea can occur. High exposures to ethylmercury in the form of thimerosal have been reported to be associated with acrodynia, renal failure, and neuropathy, consistent with chronic inorganic mercury toxicity [41]. Thimerosal used as preservative in vaccines, with recent vaccines containing (if any) up to 0.01%, is safe. The only potential adverse effect documented in nearly 70 years of use in humans is a hypersensitivity reaction in a small number of cases [54]. A World Health Organization advisory committee concluded that it is safe to continue using thimerosal in vaccines [55]. Dermal exposure may cause dermatitis [50, 56].

Diagnosis

In measuring mercury concentrations in blood and urine, it is essential to use mercury-free collection materials; generally, it is best to obtain blood and urine containers from the performing laboratories. There is not a good correlation between blood and urinary mercury concentrations and clinical manifestations. There is considerable overlap in the concentrations of mercury found in the normal population, asymptomatic exposed individuals, and patients with clinical evidence of poisoning.

Urine Mercury Concentrations

Elemental and inorganic mercury exposure can be measured by determining urinary mercury

concentration, preferably using a 24-h urine collection rather than a spot urine level. If spot collection is used, adjustment for the creatinine concentration is essential. Provocative chelation should not be used as a diagnostic test [57, 58]. In chronic mercury exposure, the urinary excretion rate reflects the kidney content of mercury [2]. Urine mercury values have their greatest utility in confirming exposure and monitoring the efficacy of chelation therapy. Urine mercury concentrations less than 20–25 $\mu\text{g/L}$ (<100 – 125 nmol/L) are considered normal, although in occupationally unexposed persons, levels greater than 10 $\mu\text{g/L}$ (>50 nmol/L) (approximately 5-nmol/mmol creatinine) are seldom found [59]. Urine mercury concentrations greater than 100 $\mu\text{g/L}$ (>500 nmol/L) have been associated with minor neurologic signs [41], whereas levels greater than 300 $\mu\text{g/L}$ (>1500 nmol/L) usually are associated with overt clinical features of mercury toxicity [59].

Blood Mercury Concentrations

Soon after exposure to elemental and inorganic mercury, mercury concentrations in the blood may reflect mercury exposure accurately. As soon as redistribution takes place, these levels become less reliable in predicting toxicity. As a result of the relatively high concentration of methylmercury in red blood cells, whole-blood levels are more accurate in determining the acute/total body burden of methylmercury [60]. Whole-blood mercury concentrations are usually less than 10 $\mu\text{g/L}$ (<50 nmol/L), but levels less than 20 $\mu\text{g/L}$ (<100 nmol/L) still are considered to be in the normal range [41]. However, it is important to realize that (avid) seafood consumers may have higher total mercury blood and urine levels. In a study in adult seafood consumers in Long Island, NY, USA, blood Hg concentrations were positively associated with weekly tuna steak or sushi intake and monthly or weekly swordfish, shark, or marlin intake [61]. After long-term exposure to mercury vapor, whole-blood mercury concentrations of

above 35 $\mu\text{g/L}$ (175 nmol/L) may be associated with nonspecific symptoms [62].

Additional Laboratory Tests

Relevant laboratory tests, depending on the clinical scenario, may include arterial blood gas analysis, serum chemistry assessments including renal and liver functions, complete blood count, type and crossmatch of blood if exposed to caustic inorganic mercury, and screening for urinary markers of glomerular or proximal tubular damage (proteinuria, glucosuria, aminoaciduria, enzymes such as α -*N*-acetylglucosaminidase and β_2 -microglobulin) [63].

Radiographs and Other Diagnostic Procedures

With acute inhalation of elemental mercury vapor, chest radiographs initially may show interstitial or alveolar abnormalities (e.g., “bronchial thickening,” diffuse alveolar infiltrates, and edema) [64]. Thereafter, the radiologic features of the acute respiratory distress syndrome may be apparent, as may be signs of complications (e.g., pneumothorax, pneumomediastinum, and subcutaneous emphysema). Elemental mercury is radiopaque and can be seen on radiographs after ingestion, intravenous exposure, or subcutaneous exposure. Especially after subcutaneous or IV injection of elemental mercury (repeat), radiographs are useful in estimating the extent of mercury disposition and in guiding the removal of deposits. Reported pulmonary computed tomography findings in acute mercury vapor exposure are centrilobular nodules, ground-glass opacification, and alveolar consolidation, corresponding to acute interstitial pneumonitis [65]. Depending on the mercury compound involved, the circumstances of exposure, and the clinical features, other diagnostic procedures may be done, including endoscopic procedures, electrocardiogram, cardiovascular monitoring,

pulmonary function tests, electroneuro-myography, and neuropsychologic tests.

Treatment

Immediate Considerations

Assessment and management of the patient's respiratory function, circulation, and urinary output are primary. Acute inhalational exposure to elemental mercury vapor requires monitoring for respiratory failure. Supplemental oxygen or endotracheal intubation and mechanical ventilation may be necessary. There are no known aerosolized antidotes for acute inhalational exposures. Ingestion of corrosive inorganic mercury requires the establishment of rapid vascular access and treatment to prevent serious fluid losses and shock. Caustic injury to the oropharyngeal mucosa may cause severe local edema, and endotracheal intubation or tracheostomy may be required to overcome obstruction of the airway.

Indications for ICU Admission Mercury Poisoning

Pulmonary effects after inhalation of mercury vapor

Corrosive damage to the oropharyngeal and gastrointestinal mucosa with risk of airway obstruction and hypovolemic shock

Severe central nervous system effects

Decontamination

Initial decontamination measures after skin or eye exposure are removal of contaminated clothing and copious flushing of contaminated skin and eyes. After ingestion of corrosive inorganic mercury, as with any caustic ingestion, gastric lavage is contraindicated [66]. If perforation is suspected, direct endoscopic evaluation is indicated. Activated charcoal hardly binds metallic compounds

[67]. In the absence of caustic injury, whole-bowel irrigation with polyethylene glycol may be considered until the rectal effluent is clear and the radiopaque material is absent [68] (Grade III recommendation). With elemental mercury, whole-bowel irrigation mainly needs consideration in the rare case of massive ingestion or prolonged retention of elemental mercury (Grade III recommendation). After subcutaneous injection of elemental mercury, excision of mercury deposits in affected tissues is the most important treatment. Surgically, removal of mercury deposits is also indicated for intravenous mercury poisoning, provided the sites are accessible.

Role of Extracorporeal Removal Techniques

Extracorporeal removal techniques lack efficacy in removing mercury from the body. In a case of severe mercuric sulfate poisoning chelation treatment (DMPS) in combination with continuous veno-venous hemodiafiltration, 12.7% of the estimated ingested dose was recovered in the ultrafiltrate, mainly in the first 72 h [69]. Hemodialysis may be necessary if renal failure ensues. Although plasma exchange was reported to decrease plasma mercury in a 26-year-old woman with severe inorganic mercury poisoning [70], prompt institution of chelation therapy is preferable, and extracorporeal techniques should only be instituted if they are required for management of other secondary problems such as AKI.

Specific Treatment

Nonantidotal

Corticosteroids have been administered in the case of interstitial granulomatous nephritis due to mercury poisoning. Their efficacy has not been shown in a controlled trial, however. In mercury vapor poisonings, corticosteroids do not seem to have a clear effect on the eventual outcome [64].

Antidotal

Chelating agents effective in enhancing mercury excretion contain thiol groups, which are thought to compete with endogenous sulfhydryl groups for the binding of mercury. For years, elemental and inorganic mercury poisonings have been treated with dimercaprol and penicillamine. Dimercaprol was the primary chelating agent because it mobilizes mercury from the kidneys and protects against kidney damage (Grade II-3 evidence). Dimercaprol cannot be used for the treatment of alkyl organic mercury poisoning because it might worsen neurotoxicity after redistribution of mercury into the brain [14].

Today, 2,3-dimercapto-1-propanesulfonate (DMPS) and 2,3-dimercaptosuccinic acid (DMSA) have been shown to be effective agents in reducing the body burden of mercury and protecting against renal damage [71] (Grade II-3 evidence). These chelators are water-soluble analogues of dimercaprol and have the advantages that they can be administered intravenously and orally and they have better side effect profiles compared to dimercaprol. In animal studies comparing the various chelators, the highest efficacy for mobilizing mercury from exposed renal tissue was seen with DMPS [72]. In a patient treated with DMPS and hemodialysis because of anuric renal failure, after ingestion of mercuric chloride, mercury's half-life in the initial phase of elimination was estimated at 2.5 days. In the subsequent terminal phase, it was approximately 8.1 days. In this case, the nonrenal clearance of mercury through the biliary and gastrointestinal tract accounted for more than 80% of total elimination [73]. Chelation therapy with DMPS and DMSA in a patient with severe organic mercury poisoning resulted in complete recovery except for minor sensory deficits. Mercury elimination was biphasic, with blood mercury half-lives of 2.2 and 40.5 days [74]. Thiol resins taken orally are not absorbed from the gastrointestinal tract and may increase fecal excretion by binding to methylmercury that is in enterohepatic circulation, therefore decreasing its reabsorption. However promising, results originate mainly from animal models and need further evaluation in treatment of

people with high blood methylmercury levels [75]. Prompt institution of chelation therapy is believed to be important, however. Aggressive chelation therapy with DMSA was futile in a patient with rapid neurologic deterioration 3 months after exposure to dimethylmercury. From this case presentation, it was suggested that DMSA may have a limited capacity to distribute to and chelate organic mercury when this has been deposited in neuronal tissue or that DMSA cannot reverse tissue damage [53, 76].

Some studies have investigated a possible role for *N*-acetylcysteine in the management of methylmercury poisoning [41]. A striking increase in urinary excretion of methylmercury has been reported in animal studies. In mice that received *N*-acetylcysteine (10 mg/mL) in the drinking water starting at 48 h after methylmercury administration, the excretion of mercury in urine over the subsequent 48 h was 47–54% compared with 4–10% in control animals. In mice, *N*-acetylcysteine was able to mobilize methylmercury from tissues, including the brain. Clearance of inorganic mercury was not accelerated by *N*-acetylcysteine [77]. Most methylmercury poisonings have a chronic course, however, and the efficacy of *N*-acetylcysteine in these situations is not yet established.

DMPS. At present, the chelator of choice in elemental and inorganic mercury poisoning is DMPS (Grade II-3 recommendation). DMPS has a better side effect profile than dimercaprol and there are a large number of cases where it has been successfully used in the treatment of patients. However, timing is crucial and it is important to realize that metal mobilization does not always equal metal excretion. Our understanding of how certain chelating agents may contribute to the redistribution of specific metals within the human body is still incomplete [78]. In the case of organic mercury poisoning, there are conflicting results regarding the efficacy of DMPS and DMSA, possibly depending on the timing of chelation therapy. DMPS has been used safely for years in Europe. DMSA and dimercaprol are alternatives. Indications for chelation therapy after mercury intoxication are not

firmly established [4]. Chelation therapy should be started early after significant exposure in patients with features of severe poisoning and in patients with evidence of a large mercury burden shown by biologic monitoring [41, 78]. In this technical report on mercury in the environment, the American Academy of Pediatrics points out that although severe or symptomatic mercury poisoning can be treated by chelation therapy, it remains questionable whether (or to what extent) this chelation therapy decreases toxic effects or speeds recovery [78].

DMPS can be administered intravenously, dissolved in saline 0.9%, or orally. In a case of severe mercuric chloride poisoning in an adult, a dosage regimen was 250 mg intravenously every 4 h for the first 48 h and then 250 mg intravenously every 6 h for the second 48-h period, followed by 250 mg intravenously every 8 h afterward. The intravenous regimen was followed by oral treatment: 300 mg of DMPS three times a day for 7 weeks [73]. In a patient with minimal change nephrotic syndrome due to chronic occupational mercury vapor inhalation (blood mercury concentration before treatment 151.5 nmol/L (30 ug/L), 24-h urine mercury concentration of 1925.5 nmol/day, with a markedly elevated urine mercury/creatinine ratio of 127.5 nmol/mmol creatinine), the following DMPS schedule was used: 250-mg DMPS intravenously 4 times daily for 3 days, followed by 250-mg IV 3 times daily for 2 days, 200 mg orally twice daily for 3 days, and finally a maintenance dose of 200 mg PO daily for approximately 9 weeks. In addition, he was treated with prednisolone 60 mg daily. He made a full recovery with blood and urine mercury concentrations within the normal reference range [79]. Another treatment schedule consists of intermittent 5-day courses of high doses of oral DMPS (30 mg/kg/day) in three divided doses. Given the recommendation in this paper that intravenous DMPS should be given at least initially in a dose of 30 mg/kg/day, and taking into account the bioavailability of about 40% of oral DMSA, this oral dose is not excessive [80]. The duration of therapy depends not only on concentrations of mercury in blood and urine, but to a major extent on the

clinical condition of the patient and the extent of organ recovery during chelation therapy, for instance, in case of renal injury. There are no good data defining the optimal duration of chelation therapy, and clinical judgment is more important. Although not observed frequently, adverse reactions to DMPS include rash, nausea, and leukopenia. The clinical pharmacology of DMPS is discussed further in ► Chap. 168, “Unithiol.”

DMSA. DMSA can be administered intravenously, dissolved in saline 0.9%, or orally. In adults, the dosage, validated for use in enhancing lead excretion, is 10 mg/kg three times a day for the first 5 days, followed by 10 mg/kg twice a day for the next 14 days [81]. This same dosage schedule has been used in children, although a dosage based on body surface area may be a better choice because it prevents underdosing, especially in young children under the age of five. In children, DMSA is administered at a dose of 350 mg/m² three times a day for the first 5 days, followed by 350 mg/m² twice a day for the next 14 days. Repeated administration may be necessary, with a 2-week interval between treatments. Adverse effects usually are limited to a mild, transient elevation of hepatic transaminase levels and mild gastrointestinal discomfort. It is not necessary to discontinue DMSA therapy because of transaminase elevations. The clinical pharmacology of DMSA is discussed further in ► Chap. 165, “Succimer.”

Criteria for ICU Discharge in Mercury Poisoning

Patient does not require mechanical ventilation.
Patient is hemodynamically stable.

Dimercaprol. In case DMPS or DMSA are not available, then dimercaprol is the best alternative to use. Dimercaprol certainly has proven its efficacy [78], though DMPS and DMSA are the preferred chelators because of the ease of administration and a better adverse effect profile. Dimercaprol must be administered intramuscularly. It can be administered at a dose of 2.5–5 mg/kg every 4–12 h [59]. A decreasing dosing schedule for 10 days has been used,

starting with 5 mg/kg intramuscularly once, 2.5 mg/kg intramuscularly every 8–12 h for 1 day, and then 2.5 mg/kg intramuscularly every 12–24 h thereafter. The dimercaprol–mercury chelate is excreted into bile and urine. Common side effects of dimercaprol include hypertension, tachycardia, pain at the injection site, nausea, vomiting, headache, and diaphoresis. Convulsions have been reported. Hemolysis may be induced if the patient is glucose-6-phosphate dehydrogenase deficient [14].

Special Populations

Pregnant Patients

Methylmercury is of major concern in pregnant women because of its profound fetotoxicity. Maternal exposure can lead to spontaneous abortion or severe developmental delay, deformities, mental retardation, and the clinical features described earlier [33].

Key Points in Mercury Poisoning

1. Inhalation of high concentrations of mercury vapor rapidly produces pulmonary toxicity.
2. Ingestion of inorganic mercury may cause severe corrosive damage.
3. Be aware of nephrotoxicity.
4. Whole-blood mercury concentrations may be useful in confirming acute exposure to elemental and inorganic mercury.
5. In symptomatic patients, prompt institution of chelation therapy is important.
6. DMPS and DMSA are the preferred chelating agents.
7. The three major forms of mercury (elemental, inorganic, and organic) have specific toxicity profiles.
8. A single elevated mercury concentration in blood or urine does not prove toxicity in an asymptomatic patient.

DMPS, 2,3-dimercapto-1-propanesulfonate; DMSA, 2,3-dimercaptosuccinic acid.

Elemental phosphorus has historical significance as a toxin that can cause impressive morbidity and mortality in patients with gastrointestinal (GI) or dermal exposures. Phosphorus is also recognized as an occupational toxin because of the epidemic of mandibular necrosis known as “phossy jaw” that occurred in the nineteenth century in the manufacturing of matches. Today, phosphorus exposures, either dermatological or via ingestion, are rare [1, 2]. In developing countries, however, reports of ingestion of phosphorus-containing firecrackers or pesticides, and of civilian phosphorus burns, continue to remind us of the severe toxicity of phosphorus [3, 4]. Nevertheless, it is important to recognize that elemental phosphorus can exist in different forms, with vastly different properties and toxicities. Moreover, chemically ambiguous or incorrect nomenclature can cause confusion and uncertainty when managing such exposures.

Chemistry

Phosphorus (atomic number 15) is an abundant element in living organisms, comprising about 1% of the body weight of an adult human, and plays a fundamental role in the biochemistry of life. Elemental phosphorus was the first element to be isolated since ancient times. Its discovery is credited to the alchemist Brand in 1669, who distilled urine in a quest for the mythical philosopher’s stone. It was named after the morning star (Greek *phos* + *phoros* or “light bearer”) because of its remarkable chemiluminescence. This faint green glow fascinated the alchemists and is now understood to be caused by its spontaneous oxidation when exposed to air. Indeed, it is far more reactive than nitrogen, which appears immediately above in the periodic table. Robert Boyle exploited this reactivity to ignite sulfur-tipped wood sticks, creating the first chemical matches in 1680. This ability to ignite and burn in the presence of oxygen in a controlled fashion ultimately allowed the full realization of Prometheus’ gift of fire on demand and justifies the name of “light bearer.”

The energy capture of molecular respiration in the phosphoanhydride links chaining together phosphate units into di- and triphosphates is essential to the energetics of living organisms. Phosphorus is also central to the regulation of many cellular processes and the framework of macromolecules. Together with nitrogen and potassium, it is one of the three “NPK” nutrient elements necessary and often limiting for plant growth, as denoted by the labeling convention of fertilizers (e.g., 10-20-10 representing the percentage by mass of each element) and by algal blooms in phosphate-rich runoffs. Phosphorus is thus essential to the fertilizer industry and global food production, constituting by far the major use of the element in modern times. In an irony of modern agriculture, phosphorus can also play a role in *reducing* unwanted insect growth via the organophosphorus pesticides. These compounds have special toxicological significance as potent inhibitors of acetylcholinesterase (see ► Chap. 92, “Organophosphate and Carbamate Insecticide”).

Nomenclature

Phosphorus (often misspelled *phosphorous*, which is an adjective for the element in a specific oxidation state, e.g., phosphorous acid = H_3PO_3 , which in turn is distinct from phosphoric acid, also called orthophosphoric acid = H_3PO_4) does not naturally exist in elemental form on the Earth, given its ready oxidation, nor is it available in the atmosphere. Instead, almost all phosphorus found on land exists as insoluble phosphate minerals in rock (e.g., the apatite group). Over geologic time, weathering allowed a small amount of phosphate to dissolve and become available for uptake by plants and microorganisms. Living organisms can only utilize soluble or the so-called inorganic phosphorus, which is better termed phosphate (or more precisely the orthophosphate ion, i.e., PO_4^{3-} , termed P_i for convenience), or the dimeric form pyrophosphate ($\text{P}_2\text{O}_7^{4-}$, denoted PP_i). Hospital laboratories often report a serum “phosphorus” (rather than phosphate) concentration,

Fig. 1 Allotropes of elemental phosphorus. The molecular arrangement of phosphorus atoms in the four most common allotropic forms are shown. White phosphorus

(P_4 ; also called yellow phosphorus due to discoloration and impurities) is by far the most toxic form of elemental phosphorus

analogous to reporting a carbon rather than bicarbonate concentration.

These phosphate units are esterified (i.e., connected via P–O–links) to a variety of organic molecules, including phospholipids, nucleic acids, and proteins, or crystallize into a calcium salt called hydroxyapatite (also called hydroxylapatite, $Ca_{10}(PO_4)_6(OH)_2$) which makes up most of the mass of bone and teeth. Phosphoric acid (H_3PO_4) can release three protons into solution (pKa for each dissociation 2.1, 7.2, and 12), making the anion a useful buffer in the laboratory and the food industry and the second most important buffer in blood after carbonic acid (i.e., dissolved carbon dioxide, which has two pKa of 6.3 and 10 but circulates at a 20-fold higher concentration).

The elemental form of phosphorus can exist in different *allotropic* forms, just as pure carbon can appear as graphite or diamond. These different allotropes are denoted by their color, and the corresponding molecular arrangement of the phosphorus atoms is shown in Fig. 1. By far the most reactive and dangerous form is *white phosphorus*, also called tetraphosphorus (P_4), a waxy, translucent solid in which each of the four atoms are bonded to the others in a tetrahedron. The geometry of these bonds is highly strained, making this allotrope chemiluminescent in air, highly flammable and very toxic even to skin contact. This was the allotrope isolated by the alchemists, and almost all cases of acute toxicity involve this allotrope. It must be stored under water, in which it is poorly soluble, and will ignite spontaneously

at around 30 °C. White phosphorus was used in friction matches during the nineteenth century and is still used in fireworks and incendiary munitions. It burns with a characteristic garlic odor in oxygen to produce phosphorus pentoxide (P_4O_{10}), which itself is readily hydrated to phosphoric acid in a highly exothermic reaction. It is also called *yellow phosphorus* due to discoloration as the surface ages and the presence of impurities. Somewhat volatile, chronic exposure to vapors in match manufacturing led to the occupational disease termed “phossy jaw,” or osteonecrosis of the mandible, a condition now caused by therapeutic bisphosphonate use. The need to store in airtight matchboxes, the London matchgirls’ strike of 1888 and the acute toxicity when ingested for self-harm ultimately led to white phosphorus being replaced by phosphorus sesquisulfide (P_4S_3) in the heads of “strike anywhere” matches or by a more stable allotrope, red phosphorus, on the striking surface of “safety matches.”

Red phosphorus is an amorphous network of atoms which does not ignite below 240 °C unless it is powdered. It is harder and unaffected by exposure to the atmosphere. It is used in many pyrogenic applications such as highway flares. It is also used to reduce elemental iodine in the so-called “red, white, and blue” synthesis of methamphetamine from pseudoephedrine or ephedrine in clandestine laboratories. More recently, it has gained notoriety in the illicit manufacturing of desomorphine (“Krokodil”) from codeine. Red phosphorus (“red”) is mixed with iodine (“blue”) to form hydroiodic acid, which is the ultimate reducing agent in the formation of methamphetamine from ephedrine (“white”), and desomorphine from codeine. The heating of red phosphorus and iodine generates the extremely toxic phosphine gas (PH_3), a highly toxic fumigant and pesticide discussed in detail in ► Chap. 94, “Phosphate and Phosphine” [5, 6]. Deaths during the manufacturing of these drugs have been attributed to the inhalation of phosphine gas [5]. Another similar sounding toxic gas, phosgene (CCl_2O), is completely unrelated and contains no phosphorus.

The most stable allotrope is *black phosphorus*, a lattice of hexagonally linked phosphorus atoms

similar to the structure of graphite, in which each atom is linked to three noncoplanar neighbors. These wavy sheets have some metallic properties and are rather inert and essentially nontoxic. A far less common form is *violet phosphorus*, consisting of brilliant crystals which can sublime to white phosphorus.

Biochemistry

Phosphate units play a pivotal role in nearly all biochemical pathways that characterize life. Oxidative phosphorylation captures some (~ 7.3 kcal/mol) of the chemical energy released in respiration by attaching a third P_i to adenosine diphosphate (ADP) to form ATP, the energy currency of the cell. Plants capture the free energy of light to generate ATP. When two or more phosphate units are in close proximity, electrostatic repulsion between the negatively charged oxygen atoms and competition between adjacent phosphorus atoms for electron pairs on oxygen result in a high phosphate group transfer potential or willingness to release the terminal phosphoryl group to water. The release of this phosphate unit (i.e., hydrolysis of the phosphoanhydride link) drives the otherwise unfavorable reactions of macromolecule biosynthesis, active transport, signal amplification, and muscle contraction (Fig. 2). It is estimated that an adult can consume 1 kg of ATP every 100 s during exercise. At rest, each molecule of ATP is estimated to cycle to ADP every minute, on average. An inability to maintain a high ATP concentration characterizes irreversible death.

The release of pyrophosphate from the triphosphate tail on each of the four nucleotides allows their polymerization into RNA and DNA strands, and the stability of these repositories of genetic information is attributable to the ribose-phosphate backbone of the nucleic acids. Adding P_i to diglycerides creates the phospholipids that form the cell membrane and organelles. A rich variety of kinases phosphorylate proteins, lipids, nucleic acids, and other substrates, orchestrating the expression and regulation of the genome and proteome. Indeed, phosphorus the “light bearer” not

Fig. 2 Bioenergetics of living organisms. Adenosine with three phosphate groups (adenosine triphosphate; ATP) is the “energy currency” of the living cell. The ready hydrolysis of the phosphoanhydride links joining two or more phosphate groups (denoted by the *red squiggle*) provides the driving force for many processes essential to life, including synthesis of macromolecules, membrane pumps, and muscle contraction. It can also transfer a

phosphate group (P_i) to other molecules including nucleotides, proteins, lipids, and carbohydrates at key junctures of metabolism. The nucleotide triphosphates release pyrophosphate (PP_i) to be added to the growing nucleic acid strand. ATP is regenerated by proton gradients developed in mitochondria and chloroplasts during oxidative phosphorylation and photosynthesis, respectively

only carries the flame of life but also controls its energy flow in an intricately complex molecular symphony. Thus, the term “phosphorus” can refer to a highly toxic allotrope such as white phosphorus, or to an essential nutrient for life, depending on the context, spelling, and chemistry. From this vantage point, the toxicity of phosphorus can now be better examined.

Uses

Elemental phosphorus is used in the production of secondary compounds like phosphoric acid or phosphate, which are then used in fertilizers, foods, beverages, cleaners, and other commercial products [7]. White (also known as yellow) phosphorus has specific uses in military ammunition, incendiary devices, fireworks, and rodenticides

[7]. For example, white phosphorus is a component in round, penny-sized fireworks, known as *catapat* (Turkey) or *diablillos* (Ecuador). Often used by children, these fireworks are common causes of phosphorus exposures [3, 8]. A dilute paste of white phosphorus is still used as an insecticide or rodenticide in some countries but has been banned in many due to its severe toxicity. It should not be confused with zinc phosphide (Zn_3P_2), aluminum phosphide (AlP), or calcium phosphide (Ca_3P_2), not with highly toxic rodenticides and fumigants still widely used to generate phosphine gas (HP_3) in the presence of atmospheric moisture or in the stomach of vermin (see ► Chap. 94, “Phosphate and Phosphine”).

The clandestine synthesis of methamphetamine and desomorphine (“Krokodil”) involves the use of red phosphorus as a reagent [9]. For this reason, in 2001, the United States Drug

Enforcement Agency added red phosphorus, white phosphorus, and hypophosphorous acid (H_3PO_2) to List 1 chemicals, restricting the handling and selling of these chemicals [10].

Toxicokinetics

The toxicokinetics of elemental phosphorus are poorly understood [7]. White phosphorus is lipid soluble and absorbed well via most routes of exposure, though this has not been accurately quantified. Intestinal absorption may be enhanced in the presence of alcohol or lipids [11, 12]. Evidence of systemic toxicity after phosphorus burns from dermal exposures suggest systemic absorption of phosphorus through the dermis [13].

Elemental phosphorus appears to distribute widely after intestinal absorption. Phosphorus is initially concentrated in the liver and then later in the bone, kidneys, brain, and heart [7, 14]. Animal studies suggest that phosphorus excretion is primarily renal, with a minor component excreted in the feces [7, 15].

The severely toxic dose of white phosphorus is reportedly on the order of 1 mg/kg, though a 1930 textbook describes a child dying from the ingestion of only 3 mg [12, 16]. The historical reputation of white phosphorus matchsticks from the nineteenth century was that ingesting the contents of one matchbox was sufficient to kill an adult.

Pathophysiology

White phosphorus exposures, be they dermal, inhalational, or enteral, are associated with severe systemic toxicity. The exact mechanisms underlying the systemic toxic effects of phosphorus, however, are not entirely clear [17]. Phosphorus is often cited as being a “general protoplasmic poison.” Much of this reputation is based on electron microscopy observations in a 1969 study in which the earliest morphologic changes were noted in the rough endoplasmic reticulum, before any changes were observed in the nucleus or mitochondria [18].

Elemental phosphorus can alter ribosomal function and protein synthesis [19, 20], lipoperoxidation [14], and triglyceride secretion [21, 22]. On histology, one sees intracellular lipid accumulation in multiple organs, namely, the liver, heart, brain, and kidneys.

Dermal Effects

White phosphorus injury produces a combined thermal and chemical burn. When exposed to air, it spontaneously oxidizes to phosphorus pentoxide, which hydrolyzes to form phosphoric acid. Thermal burns result from these two exothermic reactions. Moreover, white phosphorus particles spontaneously ignite at temperatures above 30 °C [2, 23]. Any phosphorus particles embedded in a wound may continue to oxidize and lead to ongoing tissue injury even after the initial exposure has ended [24]. While some authorities suggest this component is negligible [23], phosphorus pentoxide is intensely hygroscopic, leading to rapid tissue dehydration. The result is a severe combination of chemical and thermal injury. Hospital stays are longer and wounds heal more slowly in patients with white phosphorus burns compared to patients with simple thermal burns [24, 25].

The systemic effects of white phosphorus burns include hypocalcemia and hyperphosphatemia, leading to ECG changes and bradydysrhythmias. Rarely, systemic toxicity may develop after dermal exposures to white phosphorus, including liver and renal damage, metabolic abnormalities, dysrhythmias, and sudden death [26, 27]. They have been well characterized in animals, but only a few human cases have been reported [13]. Whether these effects represent the sequelae of the burn or of systemically absorbed phosphorus is unclear.

Gastrointestinal Effects

Ingestion of white phosphorus generally causes significant gastrointestinal irritation as a result of its direct corrosive action on the local gastric

mucosa. Mechanisms similar to the dermal injury are likely involved. Within hours of ingestion, most patients develop nausea, vomiting, and abdominal pain or cramping [11, 12, 28, 29]. Gastrointestinal bleeding also has been reported [1, 11, 12]. Endoscopy findings include erythema, inflammation, erosions, and frank necrosis [12, 29, 30]. Occasionally, patients present without any significant gastrointestinal effects, so their absence does not rule out a significant ingestion [11, 29].

Inhalational Effects

As white phosphorus is known to rapidly oxidize in air, phosphorus smoke and the vapors in phosphorus factories likely contain a mixture of phosphorus oxides and unburned phosphorus particles [7]. Inhalation of these substances may cause irritation of the mucous membranes and respiratory tract, leading to cough, hoarseness, wheezing, and laryngeal edema or inflammation. The mechanism of injury is likely due to a combination of heat formation from the oxidation of phosphorus, and hygroscopic or caustic injury caused by the products of this reaction. Animals exposed to high concentrations of phosphorus smoke have developed severe respiratory tract lesions, and some have died [7]. Historically, chronic inhalational exposure to phosphorus fumes led to “phossy jaw” or mandibular osteonecrosis. Chronic inhalational exposures can also lead to anemia, leukopenia, and chronic cough [7].

Clinical Presentation

Classically, the clinical presentation of acute elemental phosphorus ingestion was described in a three-stage model [11, 12]. In the first stage, gastrointestinal symptoms predominate, likely a result of the direct corrosive injury of white phosphorus on the GI mucosa. Patients experience nausea, vomiting, abdominal pain, and diarrhea. There are many case reports of emesis and stools emitting a luminescent glow, or even smoke. Some authors have reported a garlic odor to the

emesis or stools. The first stage is believed to last approximately 24 h. During this time, a proportion of patients can have sudden cardiovascular collapse and succumb [11, 17]. Some authors have speculated that the sudden death occurs in patients who ingested larger amounts of phosphorus, and that the etiology is direct vascular toxicity. Next, from approximately days 1 through 4, a patient may enter a period of relatively quiescent symptoms. Stage 2 has reportedly lasted until 10 days [12]. Finally, the third stage presents, with multi-organ failure, most notably acute liver failure, acute renal failure, encephalopathy, coagulopathy, arrhythmias, and cardiogenic shock.

This three-stage model may likely be the exception rather than the rule. Authors have described many presentations where stages 1 or 2 are often difficult to recognize [11, 29]. The highest mortality is observed early, among patients who do not have time to develop jaundice or a clear-cut picture of hepatic damage [11].

Gastrointestinal Effects

Initial symptoms after white phosphorus ingestion include nausea, vomiting abdominal pain, and, less frequently, diarrhea. Patients can also present with hematemesis. In certain cases, hematemesis has been reported to occur later in the course of illness, on days 3 or 4, presumably because of abnormal coagulation [11]. The GI contents have been reported to luminesce (“phosphoresce”) or to “smoke,” likely due to the continued oxidation of phosphorus on re-exposure to air [28, 29].

Renal Effects

Patients with acute phosphorus poisoning develop renal toxicity within days of the exposure. Oliguria, hematuria, proteinuria, pyuria, and the presence of hyaline casts suggest a component of acute tubular necrosis which underlies the renal toxicity. In fact, animal studies/biopsies have shown tubular necrosis, cortical necrosis, and fatty infiltration [31]. In patients who survive, the acute renal failure often resolves within days.

Neurologic Effects

Altered mental status and coma are reported in association with phosphorus poisoning and can occur in the absence of any GI symptoms [11, 29]. Rarely, seizures and myoclonic twitching have been reported. Neurologic abnormalities are associated with worse prognosis. The etiology of neurologic dysfunction is likely at least in part due to other organ abnormalities, for example, hepatic encephalopathy secondary to the associated hepatic injury, as well as shock. However, accumulation of fat in the ganglion cells, glia and vessels of the brain, as well as pericellular coarse incrustations in the outer Golgi nets of the inferior olives suggests a direct toxic effect of phosphorus on the nervous system [32].

Cardiovascular Effects

White phosphorus poisoning can cause cardiovascular collapse within 24 h of ingestion, attributed to a direct toxic effect on the myocardium and on peripheral vessels worsened by intravascular volume depletion [20]. A case series of 55 patients with acute phosphorus toxicity reported electrocardiographic T wave inversion were most common and ventricular fibrillation within the first twenty-four hours in two cases with large ingestions [33]. Other transient ECG abnormalities due to electrolyte and renal abnormalities may also develop, including prolonged QT interval, bradycardia, and ST segment abnormalities [4, 34].

Hepatic Effects

Phosphorus is recognized as a potent hepatotoxin. Patients who survive the initial neurologic and cardiac stress of acute poisonings may manifest hepatotoxicity with hyperbilirubinemia, coagulopathies, hypoglycemia, and elevation in transaminases [1, 11, 29, 31, 36, 43]. These biochemical abnormalities usually worsen over several days, though there is evidence of liver abnormalities on histopathological studies early

on [12, 14, 43]. The acute hepatic injury will resolve over several weeks. Most survivors do not have permanent hepatic sequelae, although there are reports of residual cirrhosis, fibrosis, and scarring.

With ingestion of white phosphorus, the hepatic injury pattern is classically periportal [14, 31, 43]. Fatty infiltration has been noted within 6 h and cytoplasmic damage is reflected by the endoplasmic reticular changes noted above [18–20]. Other studies show extensive necrosis, ballooning degeneration, and steatosis [17].

There are also case reports of biochemical and clinical cholestasis developing after ingestion of phosphorus [35, 36].

Hematologic

In retrospective case series, patients with phosphorus exposures were reported to have leucopenia and leukocytosis [11]. Newer case reports describe patients with myelosuppression after ingesting phosphorus, including patients with considerable decreases in granulocyte counts that resolved spontaneously [37, 38]. The precise etiologies of myelosuppression associated with phosphorus exposures are unclear but may involve either direct bone-marrow suppression or immune-mediated destruction.

Dermatologic

When white phosphorus contacts exposed skin, necrotic and yellowish full-thickness burns can result due to both chemical and thermal injury [39, 40]. They have been reported to have a garlic odor [4]. Dermal exposures to phosphorus create complex injuries that are seen mainly in the military, yet have also been reported in civilians [4]. Phosphorus particles can embed themselves in a wound and combust, leading to smoke that is a strong irritant to mucosal surfaces [23].

Systemic toxicity may develop including hypocalcemia, hyperphosphatemia, dysrhythmias, [4, 13] and hepatic and renal dysfunction [2, 23, 26, 41].

Notably, there is significant mortality associated with dermal exposures. In rats, 12–15% surface area burns were associated with 50% mortality [41]. Similar reports of sudden death in humans with similar burn areas are reported [13].

Prognosis

It is generally well accepted that there is a dose–response to phosphorus toxicity and that patients with larger ingestions will have worse outcomes. Patients developing altered mental status within the first 24 h tend to do poorly. Survival for 3 days is a good prognostic sign, though late deaths from cardiac, hepatic, or renal failure can still occur [16, 33].

Diagnosis

There are no specific laboratory findings to establish a diagnosis of phosphorus poisoning. Serum elemental phosphorus levels are not clinically available. Serum phosphate (predominantly HPO_4^{2-} and H_2PO_4^- at physiologic pH) concentrations do not correspond to free phosphorus levels and cannot be used as a surrogate (see section “[Nomenclature](#)” above). Diagnosis is mainly done on history of exposure to a phosphorus-containing product [31]. A white phosphorus ingestion may be suggested by gastrointestinal outputs that smoke, luminesce, or have a garlic odor. White phosphorus burns are suggested by a military context involving munitions.

Treatment

There is no specific antidote for phosphorus poisoning. Treatment should be focused on decontamination, where appropriate, and supportive care. Close monitoring of patients is essential and includes cardiac and respiratory monitoring and frequent checking of potassium, calcium, and phosphate levels.

Protection of Health-Care Workers

Phosphorus in either liquid or solid form can harm health-care workers trying to decontaminate or treat a patient [39]. Caution should be exercised around all vomitus, diarrhea, and contaminated clothing for this reason. Clothing contaminated with white phosphorus should be placed under cold water to prevent combustion [16]. Smoke from oxidized phosphorus can be an irritant to the airway, GI, and conjunctival mucosa. Proper personal protective equipment must therefore include protection from such fumes and from direct skin contact when working with a patient who has potentially been exposed to white phosphorus.

GI Decontamination

There are no studies showing a benefit of GI decontamination. The literature includes reports of gastric lavage efforts performed as early as 15 min until several hours post-ingestion, often using irrigation fluids with their own potential for toxicity, including potassium permanganate and copper sulfate. There is no evidence to support the use of such fluids, and, in some cases, the associated harms are well established.

Despite the lack of rigorous evidence, we believe that the potential benefit of gastric lavage likely outweighs the risk when done shortly after a large ingestion of white phosphorus (Grade III recommendation). This recommendation applies only to the white phosphorus allotrope and only for ingestions on the order of 1 mg/kg, given the associated mortality despite supportive care [16, 42]. Minimizing the introduction of air and keeping the free end of the orogastric tube under water is prudent given the reactivity of white phosphorus with air, but this practice also establishes a siphon effect to help evacuate the stomach. We recommend lavaging with ordinary cold tap water, which serves as a heat sink given the highly exothermic oxidation of phosphorus. While the risk of esophageal erosion from mucosal burns is a prudent consideration, there are no reports of this complication developing shortly after

ingestion. Activated charcoal is unlikely to offer specific benefit.

Supportive Care

The mainstay of phosphorus poisoning is the provision of rigorous monitoring and aggressive supportive care. Monitoring and correction of vital signs, electrolytes, and renal and hepatic function is essential. Hepatotoxicity should be anticipated with all its complications, including encephalopathy, hypoglycemia and coagulopathy. These complications should be managed as they arise with conventional measures. Phosphorus poisoning may lead to renal failure, and standard indications can be used to guide renal replacement therapy. Corticosteroids have not been shown to have a benefit [43]. Acetylcysteine has been postulated to have a role in limiting oxidant injury, but a small case series was unable to demonstrate a survival benefit [36].

The only definitive treatment of fulminant liver failure from phosphorus poisoning is liver transplant. The outcomes have been poor in patients with encephalopathy prior to transplant, rendering the decision to transplant and its timing very difficult [17].

Dermal Exposures

Treatment of dermal phosphorus exposures involves rapid decontamination and supportive measures. First aid principles involve rapidly removing and storing contaminated clothing underwater. Wounds should be covered with saline-soaked gauze to reduce exposure to air. Continuous irrigation should be initiated with cold water (Grade III recommendation).

Decontamination is important because particles of white phosphorus that remain in contact with skin continue to oxidize in the presence of air, worsening tissue damage [2, 40]. Large particles should be removed with forceps and placed in water. Wounds should be thoroughly irrigated with tap water to clean the wound and to remove

any of the phosphoric acids produced by the oxidation of phosphorus [2, 44, 45].

In the past, recommendations included irrigating wounds with a solution of copper sulfate (CuSO_4) [7]. The rationale often provided was that copper (II) sulfate would combine with phosphorus to form a black inactive salt, copper (I) phosphide (Cu_3P). In theory, this reaction would minimize the ongoing oxidation of phosphorus while also improving the visualization of particles for removal. Copper sulfate however, can cause severe systemic toxicity when the copper ion is absorbed into the bloodstream. Patients have been observed to develop massive hemolysis and even death after irrigation of their phosphorus burns with copper sulfate [46, 47]. Moreover, the likely reaction product is a different complex, copper (II) phosphorus (Cu_3P_2), which is unstable and can decompose to release both copper and phosphorus ions, each with their own toxicities [47]. As a result, recommendations to use copper sulfate irrigation should be considered obsolete.

It is essential to remove all white phosphorus particles from the wound as early as possible. Because these waxy, yellow particles may be difficult to visualize, an ultraviolet light (i.e., Wood's lamp) fluoresces the phosphorus particles, allowing for easier identification [48]. While some authors suggest a role for a dilute copper sulfate solution (0.5–1%) for particle identification, followed promptly by irrigation with water, even this practice is no longer recommended [23, 24]. Dilute solutions of silver (I) nitrate (AgNO_3) could in theory also increase visualization of phosphorus particles in a wound by forming black silver phosphide (Ag_3P) and should not be associated with the systemic toxicity caused by the copper ion [47]. Silver phosphide is stable, insoluble, and presumed to be far less toxic than elemental phosphorus, and excess silver ions do not cause hemolysis [47]. There are minimal human data, however, to support this practice. Regardless, the wound should always be rinsed copiously and thoroughly with water to remove any residual elemental phosphorus [47]. If particles of phosphorus are embedded in tissue, or

remain despite efforts to remove them, surgical debridement is necessary [48, 49] (Grade III recommendation).

After decontamination and debridement of the wound, supportive care is similar to that recommended for other burn patients, including volume resuscitation, wound care, tetanus prophylaxis, and monitoring for signs of infections and other injuries. Given the risk of electrolyte abnormalities, dysrhythmias, and liver dysfunction from systemic absorption of phosphorus, we recommend that patients with white phosphorus burns be monitored for a minimum of 24–48 h.

Phosphorus burns are also associated with slower healing and higher morbidity than a comparable thermal burn [41]. For these reasons, consideration should be given to transferring all patients with white phosphorus burns to a regional burn center [49].

Special Populations

Pediatric Patients

In developing countries, children are at risk of exposure to elemental phosphorus because of its use in firecrackers and as a rodenticide. The practice of spreading yellow phosphorus paste onto food to entice pests is particularly dangerous for children. These rodenticides are no longer sold in most developed countries. The clinical course of phosphorus poisoning is no different than in adults, and treatment should be the same.

Pregnant Patients

Anecdotally, elemental phosphorus has been used as an abortifacient. It is known to cross the placenta, but no cases of fetotoxicity or teratogenicity have been reported. We recommend, therefore, that pregnant patients be managed similar to other patients, with aggressive decontamination and supportive care.

Military Personnel

Military personnel are at risk for white phosphorus burns and inhalational exposures given the widespread use of phosphorus compounds in obscurants, incendiary devices, and munitions.

Indications for ICU Admission

Significant exposure to “white” (also known as “yellow”) phosphorus

Large phosphorus burn (>10% body surface area)

Evidence of shock

Respiratory compromise

Mental status changes

Patients with nausea, vomiting, diarrhea, or gastrointestinal bleeding after ingestion, given risk of deterioration and delayed systemic toxicity

Criteria for ICU Discharge

For patients with minimal symptoms or whose initial symptoms were exclusively gastrointestinal, the absence of signs of systemic toxicity after an adequate observation period of 24–48 h

For patients who developed signs of systemic toxicity (i.e., altered mental status, hepatic function abnormalities, cardiac disturbances, renal injury, metabolic derangements), resolution of the mental status changes and cardiac disturbances, and improving hepatic, renal, and metabolic function

Common Errors

Mistaking elemental phosphorus for the chemically dissimilar phosphine, phosphide or phosgene

Failing to appreciate the difference in toxicity for the different allotropes of elemental phosphorus, with white (also known as yellow) being far more toxic than red phosphorus

(continued)

Using a serum “phosphorus” (i.e., phosphate) concentration to manage an elemental phosphorus exposure

Searching for outdated or harmful “antidotes” such as copper (II) sulfate or potassium permanganate solutions for wound irrigation, rather than proceeding with immediate cold water irrigation and removal of visible particles

Key Points

1. Ingestions of white (yellow) phosphorus can cause corrosive gastrointestinal injury followed hours to days later by systemic toxicity with multiple organ dysfunction, particularly hepatic damage.
2. Dermal contact with white phosphorus can cause severe burns and systemic toxicity.
3. Treatment is supportive; there are no specific antidotes for elemental phosphorus.
4. Early, aggressive decontamination may help prevent systemic toxicity.
5. Health-care providers and rescue personnel should avoid direct contact with white phosphorus, and contaminated clothing and body fluids should be placed immediately under cold water to reduce spontaneous oxidation.

Thallium (Tl) was first discovered by Sir William Crooks in 1861, with its toxicity recognized shortly afterwards [1, 2]. The element is classified in group IIIA of the periodic table and forms both monovalent and trivalent compounds. Monovalent compounds such as thallium sulfate (Tl_2SO_4) and thallium acetate (CH_3COOTl) tend to be more toxic [2]. Thallium occurs naturally in various ores and is typically recovered from flue dust and residuals produced from the smelting of zinc, copper, and lead [3]. Thallium salts dissolve readily in water and are odorless and tasteless.

In the early twentieth century, thallium salts found use as both a rodenticide and medicinal agent. Therapeutic applications included the treatment of gout, syphilis, and tinea capitis [1]. Thallium was also utilized as a depilatory agent in consumer products. By the 1930s, cases of thallium poisoning were being attributed to depilatory products, pesticides, and contaminated foods [4–7]. Poisonings in the United States have dropped considerably since thallium was banned from use in rodenticides and pesticides in 1965. Similar patterns have been seen in other countries. Commercial uses are limited largely to semiconductor manufacturing, with other applications in the production of optical systems, thermometers, and photoelectric cells [3]. However, sporadic cases of malicious poisoning have been reported, along with ingestions of stored rodenticides pre-dating the 1965 ban [8, 9]. Despite a World Health Organization recommendation against the use of thallium in 1973, thallium compounds remain easily

available internationally. As a result, poisonings from contaminated food and water still occur across the world in the twenty-first century [10, 11].

Clinical Pharmacology

Thallium is absorbed by the gastrointestinal tract after oral ingestion, by intact skin, and by the lungs after inhalation [3]. Oral bioavailability can exceed 90%. Following absorption, thallium demonstrates rapid intracellular redistribution with an estimated volume of distribution (V_d) ranging between 3 and 10 L/kg [12]. Thallium concentrates in tissue with higher perfusion, such as the kidneys, liver, intestines, and lungs [12, 13]. Signs of toxicity may occur with either acute or chronic exposure. The lethal dose in humans is estimated to be between 10 and 15 mg/kg, though fatalities have been reported with doses as low as 200 mg [2, 14]. In a proposed multi-compartment model, thallium is initially (within 4 h) distributed over a central or fast exchange compartment, consisting of well-perfused organs, such as the kidney, liver, and muscle. During a second phase (4–24 h), thallium is distributed to a slow exchange compartment which includes the brain, causing thallium's neurotoxicity [15]. This concept is supported by reports of rising thallium concentrations in the cerebrospinal fluid, despite falling serum level [16]. Due to extensive subsequent enterohepatic circulation, thallium's terminal half-life is prolonged with a calculated length of 2.2 days [17]. However, a wide range of half-life values has also been reported [12].

Pathophysiology

Multiple mechanisms have been proposed for thallium toxicity. Thallium ions are monovalent, similar in size to potassium ions (ionic radii 1.44 Å for thallium and 1.33 Å for potassium). As a result, thallium can substitute for potassium in many potassium-dependent processes, such as Na^+/K^+ ATPase [18, 19]. Thallium exhibits an estimated tenfold higher affinity for Na^+/K^+ ATPase than potassium [20]. This latter fact likely

explains thallium's concentration within the intracellular space. Many other important cellular functions require potassium binding for optimal functioning and can be inhibited by thallium binding, such as pyruvate kinase [21]. In addition, thallium binding disrupts potassium-dependent stabilization of ribosomes, thus impacting normal protein synthesis [21].

Similar to other metals, thallium also inhibits the function of sulfhydryl-containing enzymes [2, 18]. As in the case of potassium-dependent targets, some of the identified targets are critical in cellular metabolism. Important examples include lactate dehydrogenase and phosphoglycerate kinase [21]. Other effects on cellular function have been observed but do not appear to be mediated by sulfhydryl binding or substitution for potassium. Thallium has been shown to uncouple oxidative phosphorylation within mitochondria. The precise mechanism is unclear as thallium does not inhibit the enzymes of the electron transport chain nor act as an ionophore at the inner membrane [22]. Morphological studies have corroborated membrane disruption in mitochondria, as well as other subcellular organelles such as the endoplasmic reticulum [2].

Lastly, thallium forms an insoluble complex with riboflavin, a process once utilized to isolate riboflavin from milk [23]. It has been proposed that functional riboflavin deficiency may be responsible for some aspects of thallium toxicity (e.g., dermatitis, neuropathy, alopecia) [23, 24]. Animal studies, though, have shown that riboflavin supplementation does not prevent or ameliorate thallium toxicity [25]. There are no published reports of human thallium poisoning where simultaneous assessment of riboflavin deficiency was made.

Clinical Presentation

Thallium poisoning produces a wide array of clinical manifestations, likely due to its wide distribution. The classic triad of findings includes:

- Acute gastroenteritis
- Polyneuropathy
- Alopecia

Table 1 describes the typical time course of findings, classified as early, intermediate, late, and chronic manifestations. It is important to note that the timing and order of signs or symptoms may vary depending on the severity and chronicity of thallium exposure. Patients have been known to present days to weeks later following ingestion [1, 5, 6, 11].

In the early phase (within hours), gastrointestinal disturbances, such as nausea, vomiting, abdominal pain, gastrointestinal bleeding, constipation, and diarrhea, predominate [1, 2, 14].

Autopsy findings in fatal cases have demonstrated gastric hemorrhage as well as diffuse necrotizing mucositis of the intestinal lining [14, 26]. The oral mucosa may also be affected following ingestion, manifesting with stomatitis and bluish discoloration of the gingiva [5, 27].

In the intermediate phase (hours to weeks), cardiac and neurologic manifestations become apparent. Cardiac signs, such as sinus tachycardia, hypertension, and chest pain, are the most common; bradycardia, ventricular arrhythmias, and atrial fibrillation, in the absence of structural heart disease, have also been described [1, 2, 28]. The cause of thallium's effects on the heart is probably multifactorial; some authors hypothesize a component of vagal nerve involvement [2].

Neurological signs are prominent in the intermediate phase. In some cases, these may be the first signs of poisoning, preceding any gastrointestinal symptoms [5, 10, 11]. In most cases, painful paresthesias affecting the distal extremities are the first manifestations of neurotoxicity. The lower extremities are affected before the upper extremities. Motor weakness may occur later, also localizing to the distal extremities [1–3]. Early in the course, reflexes are preserved, distinguishing thallium toxicity from Guillain-Barré syndrome, though the two can be confused if there is no known history of thallium exposure [11]. Muscle wasting may become apparent weeks after initial ingestion. Cranial nerve palsies have also been observed, with varied manifestations such as ptosis, dysarthria, dysphagia, weakened gag reflex, diplopia, and facial weakness [2, 10, 26, 29]. Cranial nerves I and VIII are not involved [26]. Additional findings include ataxia, tremor and myoclonus, blindness, and other visual disturbances [1, 2]. Neuropsychiatric symptoms resembling psychosis or delirium are also described in case reports and series [10, 27, 30]. The development of encephalopathy, coma, and seizures occurs late in severe poisoning, and generally carries a poor prognosis. Pathological examination of peripheral nerve fibers demonstrates axonal degeneration with variable damage to the myelin sheath. Nerve fibers within the spinal cord appear unaffected [26]. Nerve conduction velocity tests have shown that decreased velocities are limited to larger, fast-conducting fibers [31].

Compared to other heavy metals, thallium poisoning is associated with relatively milder renal effects. Proteinuria, as well as excretion of leukocytes and erythrocytes, may occur without an overall loss in renal function [2]. In experimental animal models, elevations of blood urea nitrogen (BUN) and loss of urine concentrating ability are detectable within 2 days of thallium exposure but normalize within 10 days. Cellular damage is localized to the thick ascending loop of Henle, with sparing of the glomeruli [20].

Dermatological changes typically occur during the late phase (2–4 weeks). Though thallium poisoning can cause a wide variety of skin changes, alopecia is the most characteristic feature [14]. Within a month of onset, alopecia may involve the entire scalp [1, 29]. Alopecia can also affect body hair areas such as the axillae, extremities, and pubis, though the medial eyebrows are spared [32, 33]. If the patient survives the acute poisoning episode, affected hair regrows over the next few months. Examination of shed hair roots may reveal a blackened appearance, though the lack of this finding should not preclude consideration of thallium exposure [8, 32]. Mees lines are another characteristic finding, due to disruption of nail formation [32, 33]. Other dermatological effects can include acne, glossitis, stomatitis, anhidrosis, palmar and plantar hyperkeratosis, and eczematous lesions [2, 14, 32, 33].

A number of persisting neuropsychiatric and ophthalmological findings have also been described in surviving patients, weeks to months following initial exposure. Memory deficits, depression, anxiety, and continued neuropathic symptoms have all been reported [11, 30]. Thallium can cause the formation of cataracts as well as retrobulbar neuritis. This latter condition may affect color vision and visual acuity, in addition to the formation of central scotoma [2].

Diagnosis

Thallium poisoning should be considered in any patient presenting with gastroenteritis, ascending polyneuropathy, and alopecia. However, as noted

earlier all of these findings may not be present simultaneously. Definitive diagnosis is made through the detection of elevated thallium concentrations in bodily fluids, typically a 24-h urine collection [18]. Reported urinary thallium levels in poisoning cases vary widely, ranging between 200 and 3000 µg/L in more recent case series [10, 11]. Normal urinary thallium levels are generally expected to be less than 1 µg/L. Regarding ancillary studies, nerve conduction studies may be helpful in confirming the presence of neuropathy. Overall, a high index of suspicion is required, as the differential diagnosis is broad and includes Guillain-Barré syndrome, systemic lupus erythematosus, botulism, poisoning by other heavy metals (arsenic, lead, selenium), other toxic exposures (chronic alcoholism, organophosphates), thiamine or riboflavin deficiency, and, rarely, porphyria.

Common Error in the Diagnosis of Thallium Poisoning

Not considering thallium poisoning in patients who present with gastrointestinal symptoms, peripheral neuropathy, and alopecia.

Treatment

Since there are no known therapies which directly antagonize the biological effects of thallium, treatment is focused on increasing elimination via urinary or fecal excretion. Due to the relative rarity of thallium poisoning, data from controlled trials is unavailable [34].

Fecal Elimination

The most widely recommended agent to enhance fecal excretion of thallium is ferricyanoferrate (II) or Prussian blue (PB). Prussian blue is not absorbed within the gastrointestinal tract and acts as an ion exchanger for univalent cations [18]. Prussian blue can bind thallium within the gastrointestinal lumen and thereby prevent enterohepatic circulation [34]. Early

studies in rats demonstrated substantial increase in fecal thallium elimination with corresponding decrease in tissue body burden and mortality following PB treatment [35]. These findings were corroborated in multiple other animal models [2, 18]. Though clinical trial data is lacking, a number of case reports and series have described the use of PB in human cases [10, 11, 30, 36, 37] (Grade III evidence). Mortality rates may still be high despite PB therapy, particularly if there are delays in instituting medical treatment [10]. Due to the potential morbidity and mortality and paucity of other treatment options, Prussian blue should be administered in all cases of known or suspected thallium poisoning (Grade III evidence). Prussian blue, under the trade name Radiogardase, has been approved for use by the US Food and Drug Administration for thallium and radioactive cesium poisoning. The manufacturer's recommended dose is 3 g orally, three times per day. 250 mg/kg twice per day is another alternate regimen [18]. Prussian blue appears to be well tolerated, with constipation reported as the primary adverse effect [38].

Activated charcoal has also been proposed as a treatment to disrupt enterohepatic circulation of thallium. Animal studies demonstrate increased fecal thallium elimination following charcoal therapy [39]. Thallium binding by activated charcoal has also been confirmed by in vitro experiments as well [40]. Multiple dose activated charcoal has been reported to be successful in cases where Prussian blue was not immediately available [8] (Grade III evidence). Finally, while sodium polystyrene sulfate also exhibits thallium binding, this effect is likely insignificant in vivo given that the high potassium concentration within the gastrointestinal lumen means potassium will likely be the dominant binding substrate [40].

Enhanced Elimination

Despite thallium's large volume of distribution, numerous reports have been published describing the use of hemoperfusion or hemodialysis in the

treatment of thallium poisoning. Individual case data demonstrates an approximate 50% decrease in blood thallium concentrations eight hours following a hemodialysis session [41]. Continuous veno-venous hemodialysis may produce greater relative decreases in blood thallium compared to intermittent hemodialysis [37]. However, the total amount of thallium removed via dialysis may be relatively modest; in one published case, 120 h of continuous dialysis was calculated to have removed a total of 143 mg of elemental thallium in a patient who ingested 2 g of thallium sulfate (1.6 g of elemental thallium) [42]. In regards to charcoal hemoperfusion, it may only be useful at relatively lower blood thallium concentrations due to saturation of the column [43]. The actual benefit of renal replacement therapies in thallium poisoning is difficult to gauge, as patients with good clinical outcomes typically receive other therapies such as PB [27]. Despite this limited data, an expert panel recently recommended that dialysis be used in cases of severe thallium poisoning, particularly when serum thallium concentration exceeds 1000 µg/L (Grade III recommendation). It was also recommended that dialysis treatment continue until serum concentrations fall below 100 µg/L [12] (Grade III recommendation).

Historically, forced diuresis has also been described as a method to increase urinary thallium excretion [42]. As with dialysis cases, patients treated with forced dialysis also received other forms of therapy, including PB. As such, forced diuresis is not recommended in cases of known or suspected thallium poisoning.

Indications for ICU Admission in Thallium Toxicity

Depressed neurological or respiratory status
Signs of cardiotoxicity

Other Therapies

Since the severity of thallium toxicity was recognized nearly a century ago, a large number of therapies have been proposed. Based on

thallium's interference with potassium-dependent processes, potassium supplementation was purported to be beneficial in treating thallium poisoning [44]. However, subsequent reports have raised concerns of worsening mental status with potassium treatment and it is no longer recommended [45]. Early animal studies found that dithizone (diphenylthiocarbazone) could increase both fecal and urinary thallium excretion, leading to its use in treating human poisoning cases [29, 39]. Use of dithizone has been abandoned, though, due to potential diabetogenic effects [29]. Dithiocarb (diethyldithiocarbamate) is another potential chelating agent that was discontinued for safety reasons; animal studies demonstrated increased thallium distribution to the brain following dithiocarb administration [46]. Dimercaprol (British anti-lewisite) has been shown to be ineffective in increasing thallium elimination [39]. In rat studies, treatment with other thiol-containing compounds (cysteine, methionine) has been associated with increased mortality compared to controls [47].

Special Populations

Pregnant Patients

Thallium readily crosses the placenta and is a potent teratogen in both chick and rat animal models. Observed malformations include reduced body weight, hydronephrosis, and impaired skeletal development [48, 49]. However, published reports of human prenatal thallium exposure are rare, with a literature review performed in 2000 finding only 18 reports containing adequate data [36]. The reported outcomes in the affected children ranged from no apparent abnormalities to severe effects (imperforate anus, cryptorchidism, long term psychomotor retardation) [36]. Prussian blue is currently listed as a pregnancy category C drug (evidence of teratogenicity in animals, but not in humans) by the US FDA and should be used in any pregnant patient with known or suspected thallium toxicity. Nursing is not recommended as thallium is known to transfer into breast milk.

Concluding Summary

The diagnosis of thallium poisoning is made on the basis of clinical findings and elevated thallium concentrations in body fluids, typically urine. In addition to supportive care, treatment with PB should be administered as soon as possible. The dosage regimen is 3 g, three times per day, or 250 mg/kg twice daily. Multiple dose activated charcoal is an acceptable alternative if PB is unavailable. Hemodialysis should also be utilized in any cases of severe thallium toxicity. Clinicians should have a low threshold for ICU admission as outcomes are difficult to predict and patients often decompensate suddenly many days after initial presentation.

Key Points in Thallium Toxicity

1. The diagnosis of thallium toxicity is made on clinical grounds and urine thallium determinations.
2. The three hallmarks of thallium poisoning are gastrointestinal symptoms, peripheral neuropathy, and alopecia.
3. Therapy consists of Prussian blue (or activated charcoal) and extracorporeal thallium removal.

Ethylene Glycol

Ethylene glycol is a colorless, almost nonvolatile liquid with an aromatic odor that is recognizable on the breath of some victims. It is used widely as antifreeze in internal combustion engines and as a solvent in various manufacturing processes.

There are many similarities between the pathophysiologies of ethylene glycol and methanol poisoning (see ► [Chap. 88, “Methanol and Formaldehyde”](#)). Although little comparable epidemiologic data exist, ethylene glycol poisoning seems to be more frequent than methanol intoxication in the developed world, whereas methanol poisonings are far more frequent in the developing world. Besides being the “poor man’s” substitute for ethanol, ethylene glycol has also been used as suicidal agent – sometimes in “copy-cat” epidemics among young people [1, 2].

Biochemistry and Clinical Pharmacology

Ethylene glycol is rapidly and completely absorbed after oral administration. The volume of distribution is approximately 0.7 L/kg based on studies in two male patients [3], although values of 0.54 L/kg [4] and 0.83 L/kg [5] also have been reported in men.

The elimination kinetic profile of ethylene glycol has not been completely clarified. There is evidence for a saturable elimination with linear (first-order) elimination for low-to-moderate plasma concentrations (<40 mmol/L [<250 mg/dL]) with a half-life of 6 h [4]. For higher plasma concentrations, the elimination seems to approach nonlinear (zero-order) kinetics.

In one male patient, the volume of distribution of glycolate, the major circulating ethylene glycol metabolite, was calculated to be 0.6 L/kg, with an estimated intrinsic half-life of 6 h over the concentration range studied [4]. When ethylene glycol metabolism was inhibited by fomepizole, the mean endogenous half-life of ethylene glycol was 10 h and the mean elimination rate was 1.1 mmol/L/h (6.8 mg/dL/h; $n = 4$) [6]. In one patient who

was admitted numerous times, a median ethylene glycol half-life of 12.9 h (range 10.0–17.3 h) was found during antidote treatment and normal renal function, indicating both glomerular filtration and tubular secretion of ethylene glycol in the kidneys [7]. The half-life of ethylene glycol during intermittent hemodialysis was 2.4 h, whereas the glycolate half-life in two admissions were calculated to 2.4 and 3.9 h, respectively. The latter were slightly shorter than elsewhere reported: 10.4 ± 7.9 h ($n = 4$) [6], 7 h ($n = 1$) [4], and 4.5 h ($n = 1$) [8].

Pharmacokinetics of Ethylene Glycol

Volume of distribution: 0.7 L/kg

Protein binding: none

Mechanisms of clearance: hepatic and renal

Active metabolites: glycolic acid and oxalic acid far more toxic than the parent compound

Methods to enhance clearance: hemodialysis

Pathophysiology of Toxic Effects

The potentially lethal dose of ethylene glycol in untreated patients is not well established, but 100 mL is the most frequently cited approximation. A value of 1–2 mL/kg seems reasonable [9].

The primary enzyme in ethylene glycol metabolism is alcohol dehydrogenase (ADH) (Fig. 1). Similar to methanol, the toxicity of ethylene glycol is mediated by its metabolites. In contrast to methanol, ethylene glycol causes central nervous system (CNS) depression and inebriation in a manner similar to ethanol.

The mechanisms for the toxicity of ethylene glycol are not completely resolved. The role of oxalate (see Fig. 1) was originally based on the visualization of oxalate-like crystals in the urine (see Fig. 2a, b) and the development of acute renal failure. Later, it was suggested that the aldehyde metabolites – mainly glycolaldehyde – were responsible for the toxic syndrome. It has been shown experimentally that these aldehydes were able to inhibit oxidative phosphorylation, glucose

Fig. 1 The complex metabolism of ethylene glycol. *Solid arrows* represent major routes or pathways. *Dotted arrows* are theoretical or less important routes. Direct renal

excretion of ethylene glycol is a major pathway of elimination, provided that normal renal function is present. *ADH* alcohol dehydrogenase

metabolism, protein synthesis, DNA replication, and RNA synthesis; these aldehydes may also be able to oxidize intracellular sulfhydryl groups [10].

The mechanism for the renal toxicity of ethylene glycol is clearly associated with the accumulation of calcium oxalate monohydrate (COM) crystals in the kidney [11, 12]. Although older human case studies [13] and studies in animals [14] appeared to show tubular necrosis without the appearance of crystals, recent human [15] and animal studies [16] have confirmed that the insoluble COM is deposited in the renal tubules and causes the kidney damage with evidence of proximal tubular necrosis. Microscopically, necrotic damage is observed only in the presence of COM [15, 16], and metabolically, damage is

most severe in kidneys with the highest accumulation of COM [16]. In vitro studies of the toxicity of COM, glycolate, glycolaldehyde, and glyoxylate in normal human proximal tubule cells showed that only COM induced renal cell death at relevant concentrations [17], whereas none of the other metabolites including the oxalate ion had an effect on cellular viability.

As judged from experimental studies, there may be no major differences in the way rodents and humans handle ethylene glycol. This idea is based on the fact that both become acidotic and display kidney injury after exposure. As such, the measurement of the ethylene glycol metabolites in rodents may also have some validity in humans [18]. In experimental studies with ethylene glycol-intoxicated rats, dogs, and monkeys,

Fig. 2 Typical needle-shaped calcium oxalate monohydrate (COM) crystals in the urine during ethylene glycol poisoning (**a**) (Regular HE-staining). Envelope-shaped calcium oxalate dihydrate crystals (**b**) are less frequent but may occur in early stages of poisoning (Polarized light) [4]

neither circulating glycolaldehyde nor glyoxylate was detected using gas chromatography–mass spectrometry techniques [18–20]. In addition, in six patients poisoned with ethylene glycol, plasma glyoxylate levels were less than 1.2 mg/dL (<0.2 mmol/L), and the glycolate concentrations ranged from 100 to 175 mg/dL (17–29 mmol/L), demonstrating that of the relevant metabolites, only glycolic acid is present in the blood in amounts significant to produce the metabolic acidosis [21].

In summary, the toxicity of ethylene glycol is most probably due to a combination of the severe metabolic acidosis caused by glycolic acid and the precipitation of calcium oxalate crystals resulting in impaired organ function, especially in the kidneys (see Fig. 1). The toxicity of glycolate is probably less than that of formate, the major toxic metabolite in methanol poisoning [9, 22]. Hypocalcemia and the resulting tetany and

seizures are probably less important mechanisms of toxicity (see Fig. 1).

Clinical Presentation and Life-Threatening Complications

Many authors describe the clinical syndrome of ethylene glycol poisoning in three stages: (1) CNS depression, (2) cardiopulmonary complications, and (3) renal failure. Although there is some support for this classification, especially for the understanding of the pathophysiology, there is considerable clinical overlap between stages.

Ethylene glycol poisoning is characterized by an initial CNS depression phase associated with inebriation progressing to coma. After 4–12 h, signs and symptoms resulting from the metabolites appear if ethanol has not been coingested. The increasing accumulation of glycolic acid leads to metabolic acidosis, which may be severe, and to compensatory hyperventilation. In contrast to methanol poisoning, these patients are usually comatose when hyperventilation is pronounced, so there is most often no subjective feeling of dyspnea. Also, for unknown reasons, leucocytosis, elevated blood pressure, and tachycardia are usually prominent features.

For the first 12–18 h postingestion, urine output is generally still adequate, and if proper treatment is started at this stage, full recovery is usually seen, although the patient may have some degree of acute kidney injury (AKI) as evidenced by elevation of serum creatinine. However, in most cases, the AKI will have a good prognosis in the long run. Another complication of calcium oxalate precipitation, such as hypocalcemia-induced tetanic contractions, may occur. The prognosis of acute renal failure is good due to dialysis therapy, although the plasma creatinine may not return to normal for weeks to months [9, 23].

Without adequate treatment, seriously poisoned patients rapidly deteriorate. In addition to CNS depression possibly associated with the inebriating effects of ethylene glycol (similar to ethanol), cerebral edema, convulsions, oliguric

renal failure, and respiratory problems may develop. Pulmonary infiltrates may be observed radiologically, but these changes are thought to be noninfectious in origin. Calcium oxalate crystals have been observed in the lungs of patients who have died from ethylene glycol poisoning, as well as in brain tissue on autopsy. Given this observation, one could postulate that these changes may be an inflammatory reaction related to this precipitation. Although “cardiogenic pulmonary edema” is claimed to occur in ethylene glycol poisoning, this is not frequent. While the cardiac ejection fraction may be lowered (to about 40% in severely poisoned patients), this is not the major cause of the pulmonary infiltrates seen in these cases. The pulmonary capillary wedge pressure is often normal in this situation; as such, the diagnostic criteria for acute respiratory distress syndrome (ARDS) are fulfilled. The concomitant ingestion of ethanol may inhibit the metabolism of ethylene glycol to its toxic metabolites, thereby prolonging the initial CNS phase of inebriation and delaying the onset of the other clinical features of toxicity.

Patients admitted “in extremis” may survive with adequate treatment. These patients should undergo computed tomography or magnetic resonance imaging of the head to evaluate the degree of brain damage. Some of these patients develop (large) cerebral infarcts or cerebral edema resulting in brain death [3, 9], whereas patients without these findings may have excellent prognosis in spite of weeks in a coma. There are a few reports of ocular manifestations and methemoglobinemia associated with ethylene glycol poisoning [24, 25]. No analytic investigations were performed, however, to rule out methanol contamination of the liquid ingested. One ethylene glycol-intoxicated patient developed visual dyspraxia as a result of cerebral infarcts [3]. No objective ocular complications were observed.

Diagnosis

Ethylene glycol in biologic fluids can be determined easily by enzymatic methods [26], or by

gas chromatography [27]. Simultaneous determination of ethylene glycol and glycolate is also possible [28].

If specific analysis is not available, the use of the anion and osmolal gaps may suggest the diagnosis (see ► [Chaps. 88, “Methanol and Formaldehyde”](#) and ► [15, “Acid–Base Balance in the Poisoned Patient”](#)) [23, 29, 30]. An ethylene glycol concentration of 100 mg/dL (16 mmol/L) increases the osmolal gap by 16/0.93, or 17 mOsm/kg H₂O (see ► [Chap. 88, “Methanol and Formaldehyde,”](#) Table 1). Osmometry uses osmolality, which is expressed as milliosmoles per kilogram of water (mOsm/kg H₂O). Osmolarity is expressed as milliosmoles per liter (mOsm/L). Because serum consists of 93% water, one has to divide serum osmolality by 0.93 to compare these two parameters. Theoretically the sensitivity of the osmolal gap should be low at ethylene glycol concentrations less than 50 mg/dL (8 mmol/L). However, for unknown reasons, the osmolal gap tends to be higher than expected from the molar contribution of ethylene glycol at such low levels. A possible explanation for this could be that bicarbonate is replaced by glycolate in the “anion side” of the Gamble diagram, and this may increase the dissociation coefficient (1.86) used in the calculations of osmolality. At low ethylene glycol concentrations, the patients are usually most acidotic, and more bicarbonate is replaced by glycolate in the “anion side” (see ► [Chap. 88, “Methanol and Formaldehyde,”](#) Fig. 4).

Serum osmolality measurement must be performed by the freezing point depression method, not by the vapor pressure method. If ethanol is coingested, there may be no metabolic acidosis, or anion gap, before the ethanol is metabolized. The details of the calculation of the osmolal gap are given in ► [Chaps. 88, “Methanol and Formaldehyde”](#) and ► [15, “Acid–Base Balance in the Poisoned Patient”](#). If ethanol is present, calculation of the osmolal and anion gaps must be repeated periodically. In late stages of ethylene glycol poisoning, most of the parent compound is metabolized to glycolic acid. In this situation, the anion gap may be increased considerably, but the osmolal gap may be close to normal. As such,

a small or normal osmolal gap does not eliminate the possibility of toxic alcohol ingestion, especially in the presence of metabolic acidosis and significant anion gap [23] (see “► Chap. 88, “Methanol and Formaldehyde,” Fig. 4).

Many arterial blood gas analyzers use lactate oxidase for the enzymatic reaction, which can give a falsely elevated lactate concentration in the presence of glycolate. By subtracting the “real” level of lactate (as found by chromatography methods or by the use of lactate dehydrogenase), this “lactate gap” will indirectly indicate the presence of glycolate, hence ethylene glycol poisoning [31, 32].

Urine microscopy may reveal envelope-shaped calcium oxalate dihydrate crystals (typically in early stage) or needle-shaped calcium oxalate monohydrate crystals (typically in late stages) (Fig. 2a, b). These findings may be delayed, and a negative microscopy should be repeated if diagnosis is still unclear. About half of patients present with crystalluria on admission, and most, but not all, develop this sign later. The crystalluria may be massive and easy to detect, even by an inexperienced microscopist. In addition, there usually are erythrocytes, leukocytes, and different casts in the urine sediment [3, 33].

Treatment

Treatment of ethylene glycol poisoning should follow the well-established principles of supportive care. Activated charcoal is of no value in ethylene glycol poisoning.

Metabolic Acidosis

Although not studied in a formal clinical trial, it is generally accepted that the metabolic acidosis associated with ethylene glycol poisoning, particularly if severe, should be treated aggressively by infusion of sodium bicarbonate. In the first few hours, 600–800 mmol (milliequivalents) of bicarbonate may be needed, especially if antidotal therapy has not been initiated. Because ethylene glycol is metabolized faster than methanol, the

acidosis develops more rapidly if an ADH inhibitor (ethanol or fomepizole) is not given, in which case a so-called bicarbonate-resistant metabolic acidosis may develop. The rapid correction of acidosis in these patients may provoke tetanic signs, especially when hypocalcemia already is present.

Inhibition of Alcohol Dehydrogenase

For ethylene glycol-poisoned patients, it is critical that ethanol or fomepizole be given to inhibit the generation of toxic metabolites by ADH. (Grade II-1 recommendation) The major advantage of fomepizole compared with ethanol is its documented effectiveness, lack of CNS depression, ease of administration, and ability to reduce the need for hemodialysis [22, 34]. If fomepizole is given to a patient with ethylene glycol poisoning before renal failure develops, hemodialysis may not be necessary [34–36]. Fomepizole (molecular weight 82 g/mol) is removed by hemodialysis with a dialysance close to that of urea [37]. No drug concentration monitoring is necessary, however, during this procedure. There are only anecdotal reports defining the threshold for antidote use in ethylene glycol poisonings. However, a recent review suggests an ethylene glycol level of 10 mmol/L (62 mg/dL) as a reasonable cut-off value given no or only mild metabolic acidosis [22]. In conventional acidotic patients or patients with renal impairment, 20 mg/dL (3 mmol/L) seems appropriate, although this has not been validated. If no serum ethylene glycol concentration is available, the degree of metabolic acidosis should be considered. ADH inhibition should be undertaken if the base deficit is greater than 10 mmol/L or a progressive decrease in serum bicarbonate is seen in serial measurements. In borderline situations, one loading dose of ethanol (e.g., healthy adult with a serum ethylene glycol concentration <62 mg/dL (10 mmol/L) and base deficit <10 mmol/L) may be preferred over fomepizole, which is usually more expensive [22]. In serious ethylene glycol poisoning, however, fomepizole is the preferred antidote.

Indications for ICU Admission in Ethylene Glycol Poisoning

There should be a low threshold for patients with pronounced metabolic acidosis (>20 mmol/L base deficit). Patients may deteriorate rapidly, and early treatment with “many nurse hands” is *essential* for outcome. Treatment is complicated (bicarbonate, antidote, treatment of seizures); patients without “normal admission criteria” also should be considered for the intensive care unit in cases of significant poisoning, especially if ethanol is the antidote in use.

Dosing of Fomepizole

A loading dose of 15 mg/kg should be administered, followed by doses of 10 mg/kg every 12 h for four doses, then 15 mg/kg every 12 h thereafter until ethylene glycol levels have been reduced to <62 mg/dL (10 mmol/L). All doses should be given as a slow intravenous infusion over 30 min (dissolved in, e.g., 100 mL of isotonic saline or dextrose), or it can be given orally at the same doses. During hemodialysis, the frequency of dosing should be increased to every 4 h, whereas every 8 h is a likely sufficient dosing frequency during continuous dialysis modalities, continuous renal replacement therapy (CRRT)/continuous veno-venous hemodialysis (CVVHD)/continuous veno-venous hemodiafiltration (CVVHDF). (Grade III recommendation)

To reach a therapeutic blood ethanol level of 100 mg/dL (22 mmol/L) – see suggested dosing regimen in ► Chap. 88, “Methanol and Formaldehyde,” Table 3. The maintenance infusion should be increased or decreased according to measured blood ethanol concentrations.

If ethanol is used as an antidote, it should be given as in methanol poisoning (see ► Chap. 88, “Methanol and Formaldehyde”). The serum ethylene glycol concentration threshold for stopping

antidotal therapy has been set arbitrarily at less than 40 mg/dL (<6 mmol/L). If an ethylene glycol concentration is not readily available, an osmolal gap less than 10 mOsm/kg H_2O may be an indicative substitute value for stopping therapy, provided no metabolic acidosis or indication of renal dysfunction is present. Although the affinity of ADH for ethylene glycol is lower than that for methanol [38, 39], this makes little practical difference in therapeutic dosing.

Several studies have indicated that ethanol can significantly inhibit ethylene glycol elimination [4, 5, 8, 40]. Ethylene glycol is renally excreted. An apparent elimination half-life for ethylene glycol of 14–17 h during ethanol therapy has been shown in patients without renal failure [40], compared with an elimination half-life of 6 h without ethanol administration [4]. Similar half-lives were observed using fomepizole instead of ethanol in patients without kidney failure [7, 41]. The apparent half-life of ethylene glycol during antidotal therapy depends on urine output and the degree of renal impairment. Although fomepizole in many places has replaced ethanol as the antidote of choice in ethylene glycol poisoning [34, 35, 42], ethanol still may be used in some hospitals. Patients with CNS depression must be closely monitored if ethanol is given because this administration has been associated with respiratory arrest [40]. The American Academy of Clinical Toxicology published practice guidelines indicating that fomepizole should be the first-line ADH inhibitor in the treatment of serious ethylene glycol poisoning. Ethanol should be reserved for cases in which fomepizole is not available or the patient is allergic to fomepizole [43]. Note that celecoxib has a pyrazole structure as does fomepizole. It is unknown if there are cross reactions between the two in cases of allergic reaction to one or the other. In the case of patients who have had a significant reaction to celecoxib, fomepizole should, if needed, be administered with appropriate caution and preparation for a possible allergic reaction.

Hemodialysis

The dialysance of ethylene glycol is well documented [3, 5, 34]. As should be expected

from its higher molecular weight than that of methanol (62 d vs. 32 d), ethylene glycol is less dialyzable than the latter (130 mL/min vs. 160 mL/min, using a 1.6 m² dialyzer at blood flow of 200 mL/min) [3, 9]. The dialysance of the toxic metabolite glycolate has also been documented [6, 21]. Because ethylene glycol has no significant pulmonary elimination, hemodialysis becomes the major route of its elimination if renal failure is present and ADH metabolism is blocked. Hemodialysis offers the additional possibility of eliminating the toxic metabolites, particularly glycolate, and correcting the metabolic and electrolyte disturbances seen in these patients. There are no studies comparing the various dialysis modalities in ethylene glycol-poisoned patients, but intermittent hemodialysis is probably more effective than continuous renal replacement therapy (CRRT), as is seen in methanol poisoning [44]. In patients admitted late with established renal failure and low serum ethylene glycol levels or low osmolal gaps, CRRT may be considered especially if the patient is hemodynamically unstable.

If the patient is seen at an early stage (i.e., before severe metabolic acidosis and renal impairment have developed), hemodialysis may not be necessary, especially if fomepizole is the antidote used [7, 34, 36]. Under such circumstances, further metabolism of the glycol to its toxic metabolites is inhibited, and the glycol is excreted rapidly through the kidneys (half-life of 12–17 h). The onset of acute renal failure may require hemodialysis, CRRT, or peritoneal dialysis. The anion glycolate may have a moderate toxicity by itself, but it is a precursor for the nephrotoxic anion oxalate. As such, the degree of metabolic acidosis (reflecting glycolate levels) is an important indicator of the need for dialysis and glycolate removal [21].

As is evident from this discussion, it is not possible to establish strict indications for hemodialysis in ethylene glycol poisoning. This decision is difficult, and an experienced clinical toxicologist should be consulted. Hemodialysis may not be easily available in rural areas, and transport complications associated with critically ill patients must be taken into consideration,

especially if ethanol is the antidote given. The introduction of fomepizole also limits the need for hemodialysis. Because hemodialysis also removes glycolate, the degree of metabolic acidosis and the renal status of the patient are more important than the serum ethylene glycol concentration as such. Most patients with normal renal function and moderate metabolic acidosis (base deficit <20 mmol/L) are best treated with bicarbonate and fomepizole, even in patients with high serum ethylene glycol concentrations. The renal function of these patients must be monitored closely, however, because hemodialysis may be necessary later if oliguric or nonoliguric renal impairment develops. Patients with serum ethylene glycol levels of 558 mg/dL (90 mmol/L) and moderate metabolic acidosis [36] and in one case a patient with 700 mg/dL, a metabolic acidosis, and a high anion gap [45] have been treated with bicarbonate and fomepizole alone. Dialysis was, however, claimed to be necessary to avoid complications related to hyperosmolality in a case with serum ethylene glycol of >1000 mg/dL (161 mmol/L) [46].

When initiated, hemodialysis should be continued until the serum ethylene glycol concentration is less than 62 mg/dL (<10 mmol/L) and there are no acid–base disturbances. (Grade III recommendation). If blood ethylene glycol concentrations are not available, hemodialysis should be continued for at least 8 h, and longer if the acidosis is not corrected. If ethanol is used as an antidote, persisting acidosis indicates that too little ethanol is being given during hemodialysis. If hemodialysis is not available, peritoneal dialysis also removes ethylene glycol [47], although far less efficiently. Hemoperfusion has no role in the management of ethylene glycol poisoning.

Criteria for ICU Discharge in Ethylene Glycol Poisoning

Resolution of metabolic acidosis

Hemodynamic stability

If ethanol-treated, that treatment must be stopped, and the patient should be not inebriated

Fig. 3 Serial plasma glycolate, fomepizole, ethanol, and ethylene glycol concentrations and urinary oxalate excretion in a 35-year-old woman who presented 6 h after ingesting antifreeze in an attempt at suicide. Her initial arterial pH was 7.42. She was treated with fomepizole, underwent hemodialysis twice (initially for 4 h and subsequently for 2 h), and recovered uneventfully. To convert

the values for plasma ethylene glycol to millimoles per liter, multiply by 0.161. To convert the values for plasma glycolate to millimoles per liter, multiply by 0.132. To convert the values for serum creatinine to micromoles per liter, multiply by 88.4. To convert the values for plasma ethanol to millimoles per liter, multiply by 0.217 (From Brent et al. [34], 832–839)

The effectiveness of fomepizole and hemodialysis in an ethylene glycol poisoned patient is shown in Fig. 3. The possibility to treat an ethylene glycol-poisoned patient with normal renal function without hemodialysis during ongoing fomepizole treatment is shown in Fig. 4. The effectiveness of hemodialysis in a patient with acute renal injury and the difficulty of dosing ethanol is illustrated in Fig. 5.

Hypocalcemia and Seizures

The hypocalcemia associated with ethylene glycol poisoning may cause tetany and seizures, which should be treated with intravenous calcium gluconate (or chloride), usually 5 mmol IV each time. Calcium should not be given for hypocalcemia per se, however, because this may increase precipitation of calcium oxalate crystals in the tissues (see Fig. 1). If calcium therapy is not effective, convulsions can be treated

conventionally with benzodiazepines, or propofol/barbiturates in the most severe cases.

Pyridoxine and Thiamine

Pyridoxine and thiamine are thought to promote the alternative metabolism of glyoxylic acid to nontoxic metabolites (see Fig. 1). Data supporting this antidotal effect are sparse, however, and their use is not routinely recommended.

Prognosis

Outcomes are excellent for ethylene glycol-poisoned patients with early diagnosis and aggressive treatment. If acute oliguric or nonoliguric renal failure develops, the prognosis for the renal function is always good with normalization of serum creatinine within 2–3 weeks (rarely months). In severe cases, patients with late

Fig. 4 S-ethylene glycol in healthy female treated with fomepizole and bicarbonate alone [7]. Note probable ongoing absorption due to early admission. Note also increasing S-glycolate before – and declining S-glycolate after – fomepizole administration. Half-lives of S-ethylene glycol

and S-glycolate during ADH inhibition were 10 and 2.4 h, respectively. The excellent correlation between S-ethylene glycol and osmolal gaps is also illustrated. Conversion factor mg/dL to mmol/L: EG: 0.016, glycolic acid: 0.013 (Reprinted with permission from Hovda et al. [7])

diagnosis and treatment may experience cerebral infarcts [9, 48].

It is important to note that in some severe cases, the prognosis may seem to be rather poor based on the overall clinical situation. If proper treatment is provided, especially dialysis in the acute stage with correction of acidosis (and removal of toxic metabolites), prognosis may be good even after weeks on mechanical ventilation and dialysis for acute renal failure. Treatment in the ICU must therefore not be discontinued early in these patients. A possible explanation for this could be that the extravascular precipitation of oxalate crystals causes a massive tissue edema (also in the brain) and that it takes time for this to resolve. Also, the crystals in the tissue and the cells may dissolve over time [49], which may partly explain the pathophysiology.

Special Populations

The toxicity of ethylene glycol in pediatric patients should generally be treated in a manner similar to that in adults. The experience with fomepizole in children is limited, but cases have been published, and ethanol [8] and fomepizole

both seem to be effective antidotes in children [47, 50, 51]. Use of new drugs such as fomepizole is generally discouraged in the first trimester of pregnancy, but in a study in pregnant rats [52], no adverse effects of fomepizole were reported. However, the alternative antidote ethanol has documented ability to cause fetal harm. In a pregnant woman with severe ethylene glycol poisoning, an antidote is obligatory, and either could be used – with a preference for fomepizole [22]. (Grade III recommendation)

Common Errors in Ethylene Glycol Poisoning

Delayed diagnosis because of failing to consider ethylene glycol poisoning in the differential diagnosis of high anion gap metabolic acidosis of unknown origin

Failure to appreciate that the absence of early clinical features and the presence of normal anion or osmolal gaps do not exclude a potentially toxic ethylene glycol ingestion

Failure to give enough ethanol, if this is the antidote chosen, especially during hemodialysis

Failure to closely monitor blood ethanol concentrations, if this antidote is used

(continued)

Fig. 5 Healthy adult male presenting with metabolic acidosis of unknown origin (gave no history). Elevated osmolar (30) and anion gaps (42; base deficit 21 mmol/L) and oxalate crystalluria indicated diagnosis (ethylene glycol measured later). He was treated with bicarbonate, ethanol and hemodialysis (HD) with uneventful recovery. Note dosing problems and variations in S-ethanol during

dialysis. Also note long half-life of S-ethylene glycol after terminated dialysis (ongoing ADH inhibition) because of transient acute kidney injury (AKI; no further dialysis necessary). As such, buffer and ADH inhibition would not have been sufficient treatment in this case with AKI. Conversion factor mg/dL to mmol/L: EG: 0.016

Failure to appreciate that prognosis may be good even in critically ill patients and over long periods if correct treatment is given

Failure to stay at the bedside until bicarbonate and antidotal therapy have been initiated because time is critical in severely poisoned patients

Key Points in Ethylene Glycol Poisoning

1. Ethylene glycol toxicity is caused by its metabolites.
2. The initial step in ethylene glycol metabolism is catalysis by alcohol dehydrogenase.
3. Treatment is based on inhibition of alcohol dehydrogenase, correction of metabolic acidosis, and removal of glycol and toxic metabolites by dialysis.

Diethylene Glycol

The clinical course and the pathologic features of poisoning with diethylene glycol (Fig. 6) have been described in some reports, among which “the 1937 sulfanilamide Massengill disaster” is probably the best known [53]. In that instance, diethylene glycol (73%) was used, because of a lack of knowledge of its toxicity, as the vehicle for preparing a liquid formulation of 10% sulfanilamide to treat infections. A total of 105 deaths due to renal failure were related to this sulfonamide formulation. No oxalate crystals were reported found in the kidneys or other organs of these victims, but the variety of the oxalate crystals (not only the envelope form) was probably not known for most clinicians before 1980

[33, 54]. Except for the lack of oxalate crystals, the pathologic findings in the various organs of these victims were similar to those found in ethylene glycol-poisoned victims.

In the 1995 Haitian episode, diethylene glycol-contaminated acetaminophen syrup caused renal failure in more than 100 children with a high mortality rate [55]. A similar episode also occurred in India [56] and in Panama in 2006 where an estimated minimum of 78 deaths were associated with consumption of a diethylene glycol-contaminated cough syrup [57]. The clinical features were renal failure, hepatitis, pancreatitis, bilateral peripheral neuropathy, and coma before death. Diethylene glycol is also found in brake fluids and other consumer products, such that sporadic ingestions also occur [58]. Because of the acute renal failure, it is difficult to relate the metabolic acidosis reported in some cases [59] to possible acidic metabolites of diethylene glycol metabolism by ADH. In one case report, there is an indication of a positive effect from hemodialysis for the removal of diethylene glycol [50]. In another case report, the use of fomepizole was associated with correction of the metabolic acidosis [60]. Topical application of silver sulfadiazine contaminated with diethylene glycol to patients with burns resulted in increased anion gap metabolic acidosis and acute renal failure. All five patients in this report died despite supportive treatment and bicarbonate replacement [61]. Autopsy was performed in one patient and no calcium oxalate crystals were observed.

Pathophysiology of Toxic Effects

Experimental studies in rats exposed to diethylene glycol showed similarities to ethylene glycol toxicity [62, 63]. The animals developed metabolic acidosis, as in ethylene glycol toxicity. Mortality was reduced if the animals were treated with bicarbonate, while administration of ethanol or fomepizole both prevented metabolic acidosis and reduced mortality to nil. Later studies in animals have demonstrated that diethylene glycol is metabolized to 2-hydroxyethoxyacetic acid, which is responsible for the metabolic acidosis

[62] and further to diglycolic acid (DGA), which accumulates markedly in the kidney and is the nephrotoxic metabolite [64]. No evidence that oxalate deposition actually occurs was noted, likely because the ether is generally resistant to metabolic degradation. During the Panama epidemic, urine and serum samples were collected as part of a case-control study such that the samples were collected late in the course (post case definition) [65]. These serum and urine samples were analyzed for concentrations of diethylene glycol and its metabolites – DGA was the only metabolite that was statistically related to case status. The serum and urine samples showed no evidence of conversion of diethylene glycol to ethylene glycol in humans. As such, DGA is of likely importance in human cases also.

Clinical Presentation and Life-Threatening Complications

In humans exposed to diethylene glycol, the presence of acidosis was earlier questioned, but this may be due to the fact that these fatal cases were reported by pathologists with less emphasis on the clinical and metabolic features present prior to death [66]. Later studies have shown metabolic acidosis and gastrointestinal features followed by acute kidney injury after 1–3 days. In survivors, neurological features such as bilateral facial nerve palsy and peripheral neuropathy, coma, and death may develop after 5–7 days [67].

Diagnosis

If there is no history of ingestion of diethylene glycol, diagnosing this condition is difficult. There is no general laboratory analysis pointing to this diagnosis, except for specific analysis, which is rarely available in hospital laboratories. Clinical features that may suggest diethylene glycol would include acute kidney injury or bilateral facial nerve palsy or other neurological features. These patients should be observed for the development of metabolic acidosis (elevated anion gap), which should trigger treatment. Since the molecular weight is higher (106 g/mol, 1 g/L = 9 mmol/L which increases the osmolal gap with

Fig. 6 Chemical structures of common glycols and glycol ethers

only 10 mOsm/kg H₂O) than for the other alcohols that form toxic metabolites (methanol and ethylene glycol), calculation of the osmolal gap is likely less useful (see ► [Chap. 88, “Methanol and Formaldehyde,”](#) Table 1).

Treatment

The toxicities of ethylene glycol and diethylene glycol are similar in that the metabolic acidosis and kidney injury result from metabolism of the parent compound via ADH. At present, treatment of diethylene glycol poisoning should be as for ethylene glycol poisonings: bicarbonate and ADH inhibition should be given if metabolic acidosis is moderate or severe (base deficit > 10 mmol/L) (Grade III recommendation); hemodialysis should be performed in severely poisoned patients, especially if metabolic acidosis is pronounced (base deficit >15–20 mmol/L) or with evidence of renal injury. Assuming no protein binding of diethylene glycol and a volume of distribution close to 0.6 L/kg, this compound (MW 106 g/mol) should be removed by hemodialysis, which will correct acidosis and likely remove toxic metabolites. Because no strict treatment recommendations can be given, physicians dealing with these patients should consult a medical toxicologist or a poison center. Further

treatment is supportive. Although not documented, thiamine should be given to protect the patient from neurological complications – especially if ethanol abuse is present.

Polyethylene Glycol

The polyethylene glycols (see Fig. 6) (molecular weight approximately 400–4000 g/mol) can be liquids, but are solid when the molecular weight is greater than 1000 g/mol. The toxicity decreases with increasing molecular weight, probably as a result of poor absorption of the solid forms. In general, the toxicity is low but may be significant for the glycols with low-molecular weight. The polyethylene glycols are used as solvents or excipients for different purposes. They also are used, and well tolerated, in the electrolyte solution recommended for whole-bowel irrigation [68].

Little is known about the clinical features of polyethylene glycol poisonings, because few cases have been reported in peer-reviewed literature. The reported CNS depression, metabolic acidosis, and renal failure may point to some similarities with ethylene glycol poisoning [69].

Unexplained increased anion- and osmolal gaps were observed in three burn patients who died following a treatment with a polyethylene glycol-based burn cream. All three patients died

in acute renal failure. The concentrations of ethylene glycol found in the circulation of two patients (0.4–1.3 mmol/L) were unlikely to explain the osmolal or anion gaps; no oxalate crystals were reported in the kidney upon autopsy [70]. The authors attributed the toxicity to the effects of polyethylene glycols or their metabolites, not to ethylene glycol per se.

Treatment

The standard measures of gastric decontamination and supportive care are probably the mainstay of therapy in these rare poisonings if the patient is seen within 1 h. The efficacy of hemodialysis is hampered by the relatively high molecular weight of this group, but hemodialysis should be done if low-molecular-weight glycols are ingested (molecular weight <600 g/mol). If severe metabolic acidosis develops, fomepizole or ethanol treatment may be administered as in ethylene glycol poisoning, but the efficacy of this treatment has not been documented. Sodium bicarbonate should be given to correct severe metabolic acidosis.

Propylene Glycol

The use of propylene glycol (1,2-propanediol) (see Fig. 6) in various cosmetics has little toxicological significance. Its use as a solvent for intravenous drug formulations has shown that this compound is not completely inert from a toxicological point of view. Renal failure may result in retention of the glycol, causing CNS depression, as about 50% is excreted in unchanged form by the kidneys, whereas the rest is metabolized mainly to lactate, acetate, and pyruvate [71]. Metabolic acidosis may be pronounced because of its metabolism to lactate, and concentrations as high as 24 mmol/L (216 mg/dl) has been described when iv medications were given with propylene glycol as a vehicle [72]. One case also reports D-lactate levels up to 110 mmol/L from an overdose of propylene glycol [73]. The elimination half-life is about 19 h [74]. In two children, CNS

depression and seizures were observed after propylene glycol intoxication [75]. Propylene glycol is also found as a diluent in many drugs. One 50 year-old male with a iatrogenic overdose of lorazepam resulted in severe propylene glycol poisoning (peak level 659 mg/dL (87 mmol/L), pH 6.9, bicarbonate 5 mmol/L (5 mEq/L) and lactate 19 mmol/L). He was treated with fomepizole, continuous renal replacement therapy (CRRT) and CVVH. His metabolic acidosis resolved, but he died from anoxic brain injury [76].

Propylene glycol (molecular weight 76 g/mol) also may raise the osmolal gap (see ► Chap. 88, “Methanol and Formaldehyde,” Table 1). If lactic acidosis develops, this rare poisoning may raise the osmolal and the anion gaps. Propylene glycol concentrations of 760 mg/dL (100 mmol/L) did not cause CNS depression [77], whereas stupor and metabolic acidosis were present in a patient with serum propylene glycol concentrations of 70 mg/dL (9 mmol/L) [78]. In these two cases, the osmolal gap theoretically would be elevated by about 108 mOsm/kg H₂O (100/0.93) and 10 mOsm/kg H₂O (9/0.93). From these few cases, there does not seem to be any definite correlation between serum propylene glycol levels and toxicity.

Treatment

Treatment of propylene glycol poisoning is supportive. The effect of activated charcoal has not been documented. Hemodialysis will effectively remove propylene glycol in the rare cases where propylene glycol can cause severe poisonings [79].

Alkyl Ethers of Ethylene Glycol (Cellosolves)

The group of alkyl ethers of ethylene glycol consists of the mono alkyl ethers of ethylene glycol – ethylene glycol butyl ether (butyl glycol, Butyl Cellosolve), ethylene glycol monomethyl ether (methyl Cellosolve), and ethylene glycol

monoethyl ether (Cellosolve) (see Fig. 6). These compounds are used mainly as solvents in hydraulic fluids and in household cleaning products. Few cases of toxicity from these compounds have been published, and the mechanisms of toxicity are not completely understood. Coma, hypotension, and metabolic acidosis with hyperventilation are typical clinical signs of intoxication. The abnormal blood picture, including erythropenia, granulocytosis, hemolysis, and hemoglobinuria, seen in animals [80, 81] may also be seen in the clinical situation [82]. Until more data are available, supportive treatment is considered to be most important for this group of compounds.

Ethylene glycol butyl ether, also known as butyl glycol, poisoning has been reported after the suicidal ingestion of a window-cleaning agent containing butyl glycol and ethanol [82]. Coma and hypotension were present on admission with blood levels of ethylene glycol butyl ether and ethanol being 432 mg/L and 36 mg/L, respectively. Metabolic acidosis developed and was confirmed by the presence of the butyl glycol metabolite butoxyacetic acid and lactate. No increase in urine oxalate content was observed. The patient was treated with forced diuresis, bicarbonate, and hemodialysis. There was a suggestion of ethanol-induced inhibition of butyl glycol metabolism and a beneficial effect of hemodialysis in this patient.

In another case without concomitant ethanol ingestion, metabolic acidosis was accompanied by coma, hypokalemia, hemoglobinuria, oxaluria, and a transitory rise in the serum creatinine level in a patient who survived on supportive therapy alone [83]. The measured increased urinary excretion of oxalate and butoxyacetic acid in this case gives an indication of different metabolic pathways, one of which includes degradation of ethylene glycol butyl ether to ethylene glycol.

Two patients with methyl Cellosolve ingestion developed metabolic acidosis and coma [84]. The patient with the more severe metabolic acidosis developed slight acute renal failure, and urine oxalate crystals were observed. The other patient had no evidence of renal effect or oxalate crystals in the urine. Both patients had an uneventful recovery after treatment with bicarbonate and ethanol.

Treatment

Based on these case reports and overall theoretical considerations, it seems reasonable to treat these poisonings with supportive therapy, including possibly gastric decontamination if the patient is seen early (within 1 h), and bicarbonate to correct significant metabolic acidosis (base deficit > 10 mmol/L). Hemodialysis also seems justified if large doses are ingested and the patient is acidotic. The role of hemodialysis in these poisonings is theoretical and lacks empiric validation. The role of ADH inhibitors is controversial. Until more data are available, ADH inhibitors should be considered mostly in rare cases in which metabolic acidosis develops, to prevent an assumed formation of toxic metabolites by oxidation of the alcohol groups.

Because the role of ADH in the metabolism of these compounds is not clear, and because fomepizole is expensive in some countries, some clinicians may prefer to use ethanol. If ethanol is used, however, patients must be placed in an intensive care unit and monitored closely as described previously.

Isopropyl alcohol (isopropanol, 2-propanol, propan-2-ol, IPA) is a clear, colorless, and volatile liquid that has a bitter taste and fruity odor similar to that of acetone [1–3]. Most commonly, isopropanol is found in rubbing alcohol as a 70% volume/volume solution in water. It is important to note that not all rubbing alcohol is made with IPA, as ethanol is also used. IPA also is found in solvents, inks, drug preparations, beauty products, de-icing agents, and hand sanitizers [4, 5]. Toxic effects of IPA are seen most commonly in alcoholics, who abuse it as a cheap, readily available substitute for ethanol [5–9]. However, most exposures occur in small children who develop toxicity through ingestion of IPA or who had long or repeated contact to IPA through dermal or inhalational exposure. Occupational exposure may occur by the dermal and inhalational routes [10–12]. The primary effects of IPA toxicity are central nervous system (CNS) depression, gastrointestinal irritation, and ketosis. Treatment is symptomatic and supportive.

Biochemistry and Pharmacokinetics

IPA is a volatile secondary alcohol. It has a volume of distribution of 0.45 to 0.7 L/kg [13–15] and is metabolized to acetone via hepatic alcohol dehydrogenase (ADH) (Fig. 1). In contrast to primary alcohols such as ethanol or methanol, the secondary alcohol, IPA, is metabolized to a

Fig. 1 Conversion of isopropanol to its primary metabolite acetone. Small amounts of isopropanol are excreted unchanged in the urine and expired air

ketone (acetone) but not to a carboxylic acid (see Fig. 1).

Pharmacokinetics of Isopropyl Alcohol

Volume of distribution: 0.45–0.7 L/kg

Protein binding: negligible

Mechanism of clearance: hepatic alcohol dehydrogenase metabolism, first-order kinetics

Half-life: isopropyl alcohol, 2–8 h; acetone, 7.7–27.7 h

Solubility: miscible in water

Vapor pressure: 33 mmHg

Data from references: [13, 14, 16, 17]

Pathophysiology

Central Nervous System Depression

Central nervous system depression may occur rapidly after ingestion of IPA [8, 13, 18–20]. Peak serum concentrations of IPA occur 30–60 min after ingestion due to its rapid absorption from the gastrointestinal tract [17, 21, 22]. In contrast to other toxic alcohols in which toxicity is largely dictated by metabolite production, IPA seems to be the primary chemical responsible for CNS depression because the onset of these manifestations clinically correlates with the time to peak serum IPA levels [5, 23, 24]. Patients also tend to clinically improve with declining serum IPA levels [8, 14, 20, 22, 23, 25]. However, they can also have prolonged CNS depression, despite declining serum IPA levels [7, 16]. Most of these cases show rising serum acetone levels, which has led to the theory that acetone may be responsible

for CNS depression. Acetone is known to cause CNS depression [26–30]. The literature also reports cases of patients with initial CNS depression whose mental status improved despite increasing acetone levels [8, 31]. Therefore it seems likely that both compounds are responsible for the CNS depression seen with IPA toxicity.

Based on animal studies, IPA is estimated to have twice the intoxicating effect of ethanol at similar serum concentrations [32]. This effect may be due to the higher molecular weight of IPA compared with ethanol [13] or perhaps the additive toxicodynamic effect of the acetone metabolite.

Respiratory depression and hypotension may accompany coma resulting from IPA intoxication [13, 17, 23–25, 33, 34]. These effects are most likely the result of peripheral vasodilation and depression of the brain stem [8, 13, 14, 17, 20, 23, 25, 35]. Tachycardia is common and may be a compensatory response to hypotension [36].

Common CNS effects of ethanol ingestion, such as ataxia, nystagmus, and dysarthria, occur but are not as common in IPA toxicity [36, 37]. Diminished reflexes are commonly seen in comatose patients with IPA toxicity [17, 31, 36]. Seizures are rare but have been reported in infants [35].

Gastrointestinal Effects

IPA may cause gastritis, mucosal irritation, and, in severe cases, hemorrhagic gastritis. Patients who ingested IPA may present with nausea, vomiting, and abdominal pain. It often is reported that hemorrhagic gastritis is caused by IPA [37, 38]. However, it is not clear that hemorrhagic gastritis is any more common than the upper gastrointestinal bleeding seen with ethanol abuse. Most abusers of IPA are alcoholics, and there is considerable overlap between these two groups. Systemic toxicity has been reported after rectal administration of IPA [39–41]. In these cases, serum IPA levels were comparable to serum levels attained after oral ingestion. Elevation of serum transaminases has been reported after IPA ingestion [42].

Metabolic Effects

Acetone is the major end product of IPA metabolism (see Fig. 1). Because no acidic product is generated, the metabolic acidosis associated with other toxic alcohols, like methanol or ethylene glycol, does not occur with IPA toxicity. Ketones or, more specifically, acetone can be measured in the serum and urine of patients with IPA toxicity. Acetone can be measured in the serum within 30–60 min of IPA ingestion but may not be measurable in the urine until 180 min after IPA ingestion [8, 21]. Patients poisoned with IPA often have a ketotic or sweet smell to their breath secondary to the presence of exhaled acetone [8, 20, 43, 44].

Other Manifestations

Hypothermia has been reported after IPA ingestion and is thought to be secondary to the CNS depression and peripheral vasodilation that can accompany IPA toxicity [14, 34, 45]. Hypothermia should be ruled out in all patients with decreased mental status, especially if they are found outdoors. Hypothermia may be secondary to the toxic effects of IPA, the environment itself, or a combination of the two.

Miosis and mydriasis have been reported in patients poisoned with IPA [13, 31, 34–36, 46]. Nystagmus has also been reported but is not a specific finding with IPA toxicity [31].

Mild hyperglycemia has occurred in patients who ingested IPA. Hypoglycemia should be suspected and ruled out in all patients with CNS depression.

Renal insufficiency and renal failure have occurred secondary to hypotension and rhabdomyolysis in IPA-toxic patients [34, 42, 47, 48]. Rhabdomyolysis should be ruled out in all patients who are found comatose, especially when the duration of the coma is unknown. Coingestants should be considered in all patients presenting with altered mental status.

Contact dermatitis, allergic dermatitis, and defatting dermatitis have all been reported in patients with prolonged contact to IPA

[49–51]. This may be more common in the occupational setting. Flushing and diaphoresis, though uncommon, have been reported after ingesting IPA [19, 34, 52, 53].

Clinical Presentation and Life-Threatening Complications

Patients most commonly develop CNS depression, ketosis, and a fruity breath odor but not metabolic acidosis [5, 7]. They also may present with abdominal pain, emesis, or gastritis. Patients with IPA toxicity should be monitored closely for rapid changes in their mental and cardiopulmonary status. Hypotension and respiratory failure have occurred after large ingestions of IPA [14, 17, 23, 34, 35, 45, 48]. If not monitored closely and treated, these conditions may lead to death.

IPA exposures occur primarily by ingestion; however, dermal, inhalational, and rectal exposures resulting in toxicity also have occurred [13, 18, 24, 33, 41, 45, 46, 54, 55]. A common exposure pathway in children is by bathing or sponge bathing with IPA to lower a fever [18, 31, 35, 38, 45, 46, 54, 55]. Dermal and inhalational exposures in adults may occur in the occupational setting.

Diagnosis

Isopropyl alcohol toxicity should be considered in the differential diagnosis of CNS depression. It also should be considered in an intoxicated patient who does not smell of ethanol, has a fruity breath smell, or has an unexplained ketosis. Non-acidotic ketosis should raise the possibility of IPA or acetone ingestion in the differential diagnosis. IPA also should be considered in patients with an unexplained osmolar gap.

Serum IPA concentrations may not be readily available in many hospitals [5]. If possible, however, they should be obtained in all patients who are suspected to have been exposed to IPA. Serum concentrations can be used to document IPA exposure. The patient's overall clinical condition,

not the IPA level, should be used to judge toxicity. Levels should be drawn at least 30–60 min after the exposure to identify peak IPA levels [5, 13, 17, 22]. The best method for measuring serum IPA levels is headspace gas chromatography with flame ionization or proton nuclear magnetic resonance imaging [5]. If IPA levels are determined by ADH-based enzymatic assays, the assay may interpret IPA as ethanol and give a falsely low IPA level [5, 44]. Although IPA may be detected with breathalyzers used to measure ethanol, these levels are unreliable [56]. A possible erroneous diagnosis of IPA poisoning may occur in patients with diabetic ketoacidosis. Cases of measurable IPA in these patients have been reported, although no exposure to IPA was known [57]. It has been theorized that the acetone produced with diabetic ketoacidosis might be reduced to IPA via ADH [5, 58]. It is also possible that in these cases, there was an unrecognized IPA exposure or that a laboratory error occurred.

Serum IPA levels greater than 120 mg/dL (20 mmol/L) have been associated with deep coma [14, 19, 48, 54]. An ingestion of 90 mL (3 oz) of 70% IPA can theoretically produce a serum IPA level of 100 mg/dL (16.7 mmol/L) in a 70-kg patient. As with ethanol, chronic alcoholics may tolerate higher IPA levels [7, 59].

Serum ketone or acetone concentrations may be helpful in the diagnosis of IPA toxicity. Acetone is not usually detected in the serum until 30–60 min post-ingestion [8, 13, 43]. Detection in the urine is usually delayed for at least 3 h post-ingestion [13]. An initial non-detectable urine acetone level should be repeated in patients if there is a high index of suspicion for IPA ingestion. Acetone levels increase as ADH metabolizes IPA. Acetone should be measurable even after IPA levels are undetectable.

Laboratory tests useful in the management of IPA-poisoned patients include serum electrolytes, creatinine, glucose, and creatine phosphokinase. If a significant metabolic acidosis is present, other causes must be considered (see ► Chap. 15, “Acid–Base Balance in the Poisoned Patient”). Acetone interferes with certain colorimetric assays used to determine serum creatinine levels; this has led to reports of falsely

elevated serum creatinine levels in patients with acetone in their serum [5, 31, 60–63]. Serum osmolality and an osmolar gap may be determined. Caution must be used, however, because not only are acetone and IPA osmotically active compounds, but other substances, such as methanol and ethylene glycol, are as well [64, 65]. The absence of an elevated osmolar gap does not rule out the presence of either compound and, in clinical practice, is not useful [66, 67].

Treatment

As with all toxic ingestions, treatment should focus on the overall clinical condition of the patient. The primary treatment centers on supportive care. Because IPA is a CNS depressant, the clinician must be vigilant with respect to the ability of a patient to maintain his/her airway. If the patient is unable to maintain a patent airway, endotracheal intubation should be performed and mechanical ventilation maintained. These patients warrant continuous cardiac monitoring and pulse oximetry. In patients who are initially able to maintain a patent airway, close monitoring for respiratory compromise is advised.

Any patient with altered mental status should have a rapid bedside assessment of the serum glucose to rule out hypoglycemia. Hypoglycemia can be treated with intravenous dextrose. Intravenous access allows for normal saline administration to maintain blood pressure and ensure adequate hydration and urine output. At least 100 mg of thiamine should be administered intravenously or intramuscularly to any patient in whom nutritional status is uncertain and who may be at risk for the development of Wernicke–Korsakoff syndrome (grade III recommendation).

Hypotension can be treated initially with intravenous fluids. In adults, normal saline can be bolused in doses of 250–500 mL each. When the total amount of intravenous fluids has reached approximately 2000 mL, one should be cautious not to fluid overload the patient. If the hypotension does not respond to intravenous normal saline, an intravenous pressor is the logical next step. Adequacy of cardiac pump function can be

ascertained by bedside echocardiography. No one pressor agent has been shown to be more efficacious than others in toxicant-induced hypotension. (See ► Chap. 14, “The Assessment and Management of Hypotension and Shock in the Poisoned Patient.”) Dopamine was traditionally the pressor of first choice because of its relative ease of use and its availability as a premixed intravenous preparation. However, in contemporary practice norepinephrine is often used. There have, however, been no comparative studies between pressors in cases of IPA toxicity. The dose administered should be based on clinical response. Hypotension that does not respond to the initial pressor of choice should be reassessed and may require higher doses or additional pressors [68].

Gastrointestinal decontamination is not likely to be of benefit in IPA ingestions because IPA is absorbed from the gastrointestinal tract within 30–60 min [24]. Gastric lavage is not likely to influence this absorption and should not be done. In a patient who presents within 30 min of a large IPA ingestion, nasogastric emptying with a standard nasogastric tube may decrease the total amount of IPA absorbed. Nasogastric emptying is theoretical and has not been tested [5, 69, 70]. However, if it is done, attention to protect the airway from aspiration is recommended [5]. Activated charcoal also is of questionable benefit, especially when used in the standard dose of 1 g/kg. An in vitro model showed that a 20:1 ratio of charcoal to IPA was needed to adsorb 87–92% of the IPA [71]. It would require a large amount of charcoal to adsorb even small amounts of IPA. Using such large amounts of charcoal becomes impractical for the treating physician and dangerous for the patient. It also is of questionable efficacy considering how rapidly IPA is absorbed from the gastrointestinal tract.

Indications for ICU Admission in Isopropyl Alcohol Poisoning

Coma

Hypotension

Respiratory failure

Patients needing hemodialysis

Criteria for ICU Discharge in Isopropyl Alcohol Poisoning

Mental status returned to baseline

Normotensive without pressors

Patient maintains own airway

Oxygenation maintained without supplemental oxygen

No further need for hemodialysis

Isopropyl alcohol can be absorbed through the skin with resulting toxicity [13, 18, 35, 46]. If dermal contact is suspected, washing the skin with a mild soap and water solution is appropriate for dermal decontamination.

Because of its small volume of distribution and negligible protein binding, IPA is easily dialyzable [13]. The clearance of IPA with hemodialysis has been reported as 137 mL/min [20, 23]. The acetone metabolite of IPA also is amenable to dialysis. Hemodialysis is rarely indicated in these patients, however. It has been suggested that patients who are hypotensive due to IPA toxicity may benefit from dialysis [72]. Another suggested indication for dialysis is for patients who have serum IPA concentrations greater than 400 mg/dL (66.6 mmol/L) [13, 72]. However, most patients do well with supportive care alone, even if the patient presents with hypotension or an initially high serum IPA concentration [5, 8, 19, 34]. There are risks associated with hemodialysis, and the overall clinical picture of the patient should be considered [73]. Peritoneal dialysis has been attempted in several reported cases, but the clearance of IPA with this method was only slightly better than the patients' endogenous clearance [74]. For patients who do not respond to aggressive supportive care or who are unstable due to high levels of IPA, hemodialysis should be considered in consultation with a medical toxicologist or poison control center.

There are no antidotes for IPA toxicity. Inhibiting ADH with ethanol or fomepizole would only prolong the time for the metabolism of IPA. Because acetone itself neither is life threatening nor causes significant end-organ damage, treatment with ADH inhibition is unnecessary [75, 76].

Special Populations

Pediatric Patients

Children may have a different susceptibility to dermal IPA absorption than adults owing to their larger body surface ratio and thin dermis. IPA has been applied dermally to reduce fever in children, with resultant significant toxicity [45, 46, 54, 55]. It is unclear if the toxicity is due solely to the dermal absorption or possibly to a combination of dermal and inhalational absorption. Infants have become toxic when IPA was applied chronically to the umbilicus for cleaning [35]. Coma, hypotension, and seizures all have been reported in children with IPA toxicity [33, 35]. Children also have been noted to experience dermal irritation and chemical burns when IPA was applied to the skin [77]. Unlike ethanol, hypoglycemia has not been reported to occur in children intoxicated with IPA [78–80]. A rare case of hemorrhagic gastritis has been reported in a pediatric patient with IPA toxicity [81].

Pregnant Patients

Based on the size of the molecule, its solubility, and its similarity to ethanol, IPA is expected to cross the placenta. Hypotension in the mother is a concern for the overall status of the fetus. Supportive care for the mother is paramount for protecting the fetus. IPA is not considered a human carcinogen, and its teratogenicity to humans is unknown [82].

Common Errors in Isopropyl Alcohol Poisoning

Not considering isopropyl alcohol as a potential cause in an intoxicated patient

Ruling out the diagnosis of isopropyl alcohol intoxication based on a normal osmolality and osmolar gap

Attributing an anion gap metabolic acidosis to isopropyl alcohol

Using hemodialysis instead of good supportive care as a cornerstone of treatment

Key Points in Isopropyl Alcohol Poisoning

1. Toxicity may occur after oral, inhalational, rectal, or dermal exposure.
2. Isopropyl alcohol can be a potent central nervous system depressant.
3. The hallmark of IPA toxicity is ketosis without metabolic acidosis.
4. Isopropyl alcohol toxicity may cause gastritis as with other alcohols.
5. Treatment should focus on supportive care.

Methanol

Methanol (methyl alcohol, “colonial spirit,” “wood alcohol,” “solvent alcohol”) is a highly toxic alcohol that is widely used industrially as a solvent and in the production of formaldehyde and methylated compounds. It is found in commercial products such as gasoline, antifreeze, gasohol, windshield washer fluid, copy machine fluid, canned heat (Sterno), paint, shellac, and solvents for removing wood finishes. There also is a continuous discussion on the possible use of methanol as an alternative energy source in combustion engines.

Most cases of methanol poisoning are isolated episodes caused by accidental or intentional ingestion. Epidemics of methanol poisoning may occur when it is mistakenly substituted for ethanol by alcoholics or when methanol contaminants are used to ferment (e.g., wine) or illicitly distill (e.g., moonshine whisky) alcoholic beverages. In such circumstances, hundreds of victims have been reported [1–3]. In recent years, both medical journals and the news media have identified methanol poisonings as a frequent problem in the developing world [4–9]. This has recently resulted in the involvement of a large NGO – Doctors Without Borders/Médecins Sans Frontières (MSF) – identifying this as a global problem [9].

Biochemistry and Clinical Pharmacology

The chemical formula of methanol is CH_3OH . It is a colorless, volatile, highly flammable liquid with a density of 0.81 g/mL and a weak smell that resembles that of ethanol. Methanol is absorbed rapidly from the gut, skin, and lungs. It distributes in the total body water compartment of approximately 0.7 L/kg [10]. It is slowly metabolized first to formaldehyde and then to formic acid, which is responsible for the toxic effects in methanol intoxication (Fig. 1) [11]. The oxidation of formaldehyde occurs rapidly so that little formaldehyde accumulates in the serum. The metabolism of methanol by alcohol dehydrogenase, which accounts for about 90% of its elimination, is zero order, with a rate of 2.7 mmol/L/h (8.5 mg/dL/h) (half of that of ethanol) in one case [12]. Only small amounts are excreted in expired air and urine. The half-life of methanol is typically reported in the range of 45–80 h when metabolism is blocked by an antidote [10, 11, 13], 1.1–3.7 h during intermittent dialysis and antidote [14–17] and 8.1 h during continuous dialysis modalities and antidote [17].

The metabolism of formate depends on the folate pool [11]. Primates have a small folate

reserve and are the only animal order that accumulates formate and experiences methanol toxicity [18]. Formate can be reabsorbed in the proximal tubule cells by a H^+ /formate cotransport, as well as a nonionic diffusion of formate and indirect coupling of formate to Na^+/H^+ exchange [13, 19]. As such, the renal excretion of formate is pH dependent: The more acidotic the patient becomes, the less formate is excreted [13]: The half-life of formate is usually reported in the range of 2.5–5.0 h [13, 14, 20], but one extreme case of 77 h (2.9 h during dialysis) has been reported [21].

Toxicokinetics of Methanol

Volume of distribution: 0.7 L/kg

Protein binding: none

Mechanisms of clearance: hepatic, renal (minimal), pulmonary (minimal)

Active (toxic) metabolite: formic acid

Method to enhance clearance: hemodialysis

Pathophysiology of Toxic Effects

The lethal dose of methanol is variably given as 30–240 mL, with 1 g/kg (1.2 mL/kg) as the best

Fig. 1 Methanol metabolism. Ethanol and fomepizole inhibit metabolism by alcohol dehydrogenase. As a result of the small folate pool in primates, little formic acid is metabolized further, so it tends to accumulate in the body

estimate [11, 22]. The minimal dose that can cause permanent visual defects is unknown but most probably ingestion of more than 30 mL (adults) is necessary.

Similar to ethylene glycol, the toxicity of methanol is mediated through its metabolites. In contrast to ethylene glycol, however, methanol does not cause significant central nervous system (CNS) depression and ethanol-like inebriation. In the early stage of methanol poisoning, the toxic effects are due to the increasing metabolic acidosis caused by the accumulation of formic acid. Why the eye is the primary target organ for methanol's toxic effects is not fully understood [11, 23, 24]. Formate inhibits cytochrome oxidase, the final enzyme in the mitochondrial electron transport chain, by binding to the ferric iron in the heme moiety of that enzyme. This inhibition occurs in the 5–30 mmol/L range (16–96 mg/dL) [25], which is similar to the formate concentrations associated with retinal toxicity in humans [11] and other primates [26, 27]. Inhibition of mitochondrial energy metabolism markedly increases the production of reactive oxidative molecules and the likelihood of oxidative injury [28]. Formate also seems to increase retinal vulnerability to oxidative injury by causing a depletion of glutathione, which is the major endogenous molecule protecting against oxidative stress in the retina [29]. The retina is exposed to several sources of oxidative stress by virtue of its high intrinsic metabolic rate and its exposure to ambient radiation. Normally, retinal glutathione concentrations are relatively high compared with other organs [30]. Glutathione synthesis is highly dependent on mitochondrial respiration [31]. Studies using a folinic acid–dysfunctional rat model suggest that cones may be more sensitive than rods to long-term damage from methanol poisoning, possibly because of the greater number of mitochondria in cones than in rods [29].

In late stages, as formate accumulates, the toxicity is caused mainly by the histotoxic effects of formate, which inhibits mitochondrial respiration. The resulting lactate production increases the metabolic acidemia and toxicity of formate, as more formate is protonated and able to penetrate the blood–brain barrier [32]. A vicious hypoxic

cycle is initiated [33]. In the late stages, specific lesions of the lenticular nucleus (putamen and globus pallidus) may develop. It is not known why the lenticular nucleus is particularly vulnerable in late stages of methanol toxicity. Although the mechanism of these lesions is not known, it is reasonable to believe that the histotoxic effect of formate in late stages, causing a so-called *circulus hypoxicus*, is a contributing factor (Fig. 2). This increased lactic acidosis with increasing formate concentration was demonstrated in the recent Norwegian [34] and Czech outbreaks [3].

Clinical Presentation and Life-Threatening Complications

The classic pattern of methanol toxicity includes a latent period of approximately 12–24 h from the time of ingestion to the occurrence of signs and symptoms. This is the time it takes for sufficient amounts of formic acid to accumulate following methanol metabolism. This latent period may be longer if ethanol is coingested because the latter competitively inhibits methanol metabolism by alcohol dehydrogenase. A latent period of up to 90 h has been reported when ethanol is coingested [10]. Methanol itself has few direct effects. Mild CNS depression and ethanol-like intoxication have been reported [11] but may as well be due to the osmotic effect in the CNS. Methanol itself, however, is typically not considered to have any inebriating effects, and patients with high methanol concentrations (137 mmol/L [438 mg/dL]) also have been sober [10]. With ingestion of concentrated methanol, nausea, vomiting, and abdominal pain may develop shortly after ingestion. A few cases also may present as acute abdomen, probably because of pancreatitis [11, 12].

The first clinical features of systemic toxicity are usually a feeling of weakness, anorexia, headache, nausea, and vomiting, accompanied or followed by increasing hyperventilation as metabolic acidosis progresses [11, 22, 35, 36]. The first complaint may often be shortness of breath because of hyperventilation. Visual symptoms (blurred vision, decreased acuity, halo vision, tunnel vision, photophobia, and “snow fields”) may

Fig. 2 The “circulus hypoxic” resulting from methanol ingestion (From Jacobsen [33])

appear first or with the abovementioned symptoms. Usually ocular symptoms precede objective signs, such as dilated pupils that are partially reactive or nonreactive to light and funduscopy showing optic disk hyperemia with blurring of the margins, so-called pseudopapillitis [11, 22, 36].

If treatment is not initiated at this early stage of poisoning, the patient may develop coma and respiratory and circulatory failure. A few patients also may develop methemoglobinemia with cyanosis, probably because of an interaction between formate and the ferric moiety of hemoglobin [11].

The toxic effect on the lenticular nucleus does not lead to detectable signs and symptoms in the acute stage because it is concealed by pronounced CNS depression. Survivors may manifest a Parkinson-like syndrome due to toxic effects on the globus pallidus when they recover from the acute condition, usually after several days to a week [37, 38].

Diagnosis

Methanol poisoning can be difficult to diagnose in the absence of a history, especially if ethanol is

coingested and the latency period is prolonged. The analytical alternatives at present are measuring methanol and formate and/or using the osmolal and anion gaps. Methanol is usually detected by gas chromatography or radioimmunoassay. Formate analyses using chromatographic or enzymatic methods [39, 40] are highly specific, but until now the availability has been limited. Therefore, a dry-chemistry, strip-based analysis for bedside measurement of formate is now under development [41]. Whether the laboratory or the bedside assay is used, a simple flow chart can easily guide the clinician on admission of the patient (Fig. 3). Laboratory evaluation of suspected methanol poisoning should also include arterial blood gas analysis; complete blood count; measurement of electrolytes, blood urea nitrogen, creatinine, glucose, osmolality, and amylase; as well as a urinalysis. The history should include the amount, concentration, and time of methanol ingestion, the nature and onset of symptoms, and whether ethanol was coingested. Patients also should be carefully questioned about the presence or absence of visual complaints, gastrointestinal symptoms, and feelings of intoxication.

Fig. 3 A simple approach for clinical utility of the formate analysis in the diagnosis of methanol poisoning (Printed with permission from McMartin et al. [62])

The physical examination should focus on vital signs (especially respiratory rate) and the neurologic, visual, and cardiopulmonary status. Visual acuity and funduscopic examinations should be performed. The objective signs of ocular toxicity of methanol include dilated pupils, which are partially reactive or nonreactive to light, and optic disk hyperemia with blurring of the disk margins, and later pallor. This blurring of disk margin may look like papillary edema, but there is no diopter difference between the fundus and the disk (so-called pseudopapillitis).

Because the clinical diagnosis of methanol poisoning is difficult, methanol poisoning should be considered in every patient presenting with a metabolic acidosis of unknown origin. The general evaluation of a patient with a metabolic acidosis of unknown etiology is described in detail in ► Chaps. 2, “The Diagnostic Process in Medical Toxicology,” and ► 15, “Acid–Base Balance in the Poisoned Patient.”

The anion and osmolal gaps are indirect methods, but together they can give a clue to the diagnosis. The accumulation of formate causes a metabolic acidosis, generally with an increased anion gap [42]. Based on a study evaluating the

gaps in an unselected group of acutely hospitalized patients, the reference range of the AG ($[\text{Na} + \text{K}] - [\text{Cl} + \text{HCO}_3]$) was found to be 5–21 mmol/L [43]. Because of its low molecular weight (32 d) and the high concentrations associated with toxicity, methanol increases the serum osmolality, as do other alcohols. This effect can be detected by calculating the difference between the measured osmolality (O_m) and the calculated osmolality (O_c), $OG = O_m - O_c$:

$$O_c = [2 \times \text{sodium}] + [\text{blood urea nitrogen}/3] + [\text{glucose}/18]$$

$$O_c = (1.86 \times \text{Na} + \text{blood urea nitrogen} + \text{glucose}) / 0.93 (\text{SI units})$$

The “new” reference range for the osmolal gap in unselected patients is -9 – 19 mOsm/kg H_2O [43]. An osmolal gap greater than 19 (5 ± 2 SD) strongly indicates exogenous osmoles of some kind [1, 21]. A methanol concentration of 32 mmol/L (100 mg/dL) increases the osmolal gap by $32/0.93 = 34$ mOsm/kg H_2O . The denominator of 0.93 accounts for the serum being 93% water. The presence of ethanol influences the osmolal gap and must be subtracted. The osmolal

Table 1 Osmolal contribution from a S-concentration of 1 g/L (100 mg/dL) of relevant alcohols, glycols and acetone

	Molar mass (g/mol)	Osmolality per 100 mg/dL (mOsm/kgH ₂ O)
Methanol	32	34
Ethanol	46	24
Acetone	58	18
Isopropanol	60	17
Ethylene glycol	62	17
Propylene glycol	76	14
Diethylene glycol	106	10

contribution of various alcohols (plus acetone) is presented in Table 1.

Several conditions in medicine increase the anion gap or the osmolal gap, but except for methanol or ethylene glycol poisoning, few increase both at the same time. The exceptions include diabetic ketoacidosis (although this osmolal gap is typically reported to increase less than 14 mOsm/kg H₂O [44] and a high blood glucose can help point to the diagnosis), alcoholic ketoacidosis [45] (this acidosis will respond to intravenous fluids and thiamine), chronic renal failure [46] (the creatinine will give a diagnostic clue), or major trauma with circulatory shock [47]. By adding a “decision level” of 25 mOsm/kg H₂O for when to start antidote treatment without waiting for any further analyses, the diagnostic specificity increases further. Regarding the sensitivity, *no level of osmolal gap as a single test can exclude toxic alcohols as the cause* (Fig. 4) [34].

In late stages of methanol poisoning, most – sometimes all [3] – of the methanol already has been metabolized to formate [34]. At this stage, the anion gap is elevated, but the osmolal gap is normal; formate detection is the only way to confirm the diagnosis. In early stages, or if ethanol is coingested, only the osmolal gap is elevated because the metabolism of methanol to formate has not yet begun (Fig. 4) [34]. If the diagnosis is based on the osmolal and anion gaps, osmometry must be performed by the freezing point depression technique and not by the vapor pressure technique

Fig. 4 The correlation between methanol and the osmolal gap and formate and the anion gap (Printed with permission from Hovda et al. [34])

because the latter does not detect the increased osmolality caused by volatile alcohols [36].

Increased anion and osmolal gaps also occur in ethylene glycol intoxication. Figure 5 enumerates various other causes of increased osmolar or anion gaps. Differentiating the two (methanol and ethylene glycol) may be difficult, but the treatments are essentially the same. Hypocalcemia, seizures, and urine oxalate crystals indicate ethylene glycol poisoning; optic disk hyperemia indicates methanol poisoning [1].

Computed tomography or magnetic resonance imaging of the brain may show necrosis of the putaminal areas, a finding seen late in the course of methanol poisoning [36–38, 48]. Diffusion-weighted MRI can provide a much earlier detection of cytotoxic edema in the same regions of the brain [49].

Treatment

Gastric decontamination is unlikely to be beneficial because methanol is rapidly and completely absorbed, and most patients do not present before onset of clinical features. Supportive treatment follows the established principles of intensive supportive care.

Fig. 5 Causes of an increased anion gap and osmolal gap. Elevations in both gaps strongly indicate methanol or ethylene glycol intoxication

The specific treatment of methanol poisoning includes bicarbonate to counteract the metabolic acidosis, ethanol or fomepizole to inhibit methanol metabolism to formate, and selective hemodialysis (intermittent high-flow (IHD) or continuous modalities (CRRT)) to remove methanol and formate. Folic acid or folinic acid (leucovorin) is of theoretical value in increasing the metabolism of formate (see Fig. 1), but the clinical utility of this effect has not yet been proven [15, 50]. The standard dose of folinic acid is 50 mg intravenously four times a day. See ► Chap. 149, “Folic and Folinic Acids” for information regarding the clinical pharmacology of these antidotes.

Correction of Metabolic Acidosis

Although not prospectively studied, most clinical toxicologists recommend that the metabolic acidosis be treated aggressively by infusing sodium bicarbonate; 500–800 mmol (mEq) or even more may be required during the first few hours. The goal should be full correction of the acidosis (Grade II-2 recommendation), which will require more bicarbonate the more acidotic the patients are, because of the need to buffer the proteins [51]. Bicarbonate treatment decreases the amount of non-dissociated

formic acid, resulting in less access of formate to the CNS [22, 32]. In contrast to other types of metabolic acidosis, metabolic acidosis resulting from methanol poisoning should therefore always be treated aggressively with bicarbonate. For acidotic methanol-poisoned patients, alkali treatment must be accompanied by ethanol or fomepizole; otherwise, the acidosis becomes bicarbonate resistant, as more formic acid is produced from the metabolism of methanol (see Fig. 2).

Indications for ICU Admission in Methanol Poisoning

Severe metabolic acidosis (manifested by a base deficit >20 mmol/L)

Need for hemodialysis

Significant clinical manifestations

If ethanol is used as an antidote (due to dosing and monitoring difficulties)

Inhibition of Formation of Toxic Metabolites

For antidotal treatment criteriae – see Table 2. Central to the treatment of methanol poisoning is

Table 2 Antidote treatment criteria^a (Adapted with permission from McMartin KE, Jacobsen D, Hovda KE. Antidotes for poisoning by alcohols that form toxic metabolites [62])

	Recommended criteria
I	Serum methanol concentration ≥ 10 mmol/L (32 mg/dL) ^b
II	Documented/suspected recent history of ingestion with an osmolal gap ≥ 25 mOsm/kg H ₂ O ^c
III	Documented/suspected history of ingestion plus two or more of the following criteria
	A: Arterial pH < 7.3
	B: Serum bicarbonate < 14 mmol/L or base deficit (BD) > 10mmol/L
	C: Osmolal gap > 25 mOsm/kg H ₂ O ^c
	D: The presence of visual disturbances

^aAntidote should be given without delay, if toxic alcohol cannot be excluded as the cause. No osmolal gap will be able to exclude toxic alcohol as the cause

^bOnly if there is no significant metabolic acidosis (Base deficit < 10 mmol/L (10 mEq)) or no indications of organ toxicity

^cOG calculated after the ethanol contribution is subtracted

the inhibition of its metabolism to toxic metabolites (see Fig. 1). Guidelines suggest fomepizole being the antidote of choice, while ethanol can be used if fomepizole is unavailable; [52–55] however, no definite improved outcome with fomepizole has been documented yet [56, 57]. Clearly, the preference for fomepizole is mainly based on simplicity of use [58, 59], efficacy [53, 60], and lower degree of adverse events [61]. In some countries, for example, the USA, the acquisition costs of fomepizole and 100% ethanol are similar. In other countries, there is a higher acquisition cost of fomepizole which limits its use, especially in the developing world [62].

Regardless of the antidote used, early initiation of antidotal treatment is crucial. Zakharov et al. found a positive association between pre-hospital ethanol administration and improved clinical outcome during the methanol outbreak in the Czech Republic [63]. This is particularly important during mass outbreaks or with long transporting distances to hospital facilities with ICU and dialysis capacity.

Fomepizole. Fomepizole (chemically 4-methylpyrazole), the frequently used antidote

for the treatment of ethylene glycol poisoning [64, 65], is also documented for use in methanol poisoning [52, 66, 67]. As in ethylene glycol poisoning, the major advantage of fomepizole is its documented effectiveness, lack of CNS depression, ease of administration, few side effects, and ability to reduce the need for hemodialysis [62]. The lack of pancreatitis, a well-known side effect of ethanol, also makes fomepizole a more attractive antidote because pancreatitis is sometimes reported in methanol-poisoned patients [68]. Fomepizole can be administered intravenously or orally, although most, not all, pharmaceutical preparations are for intravenous administration [69]. If administered intravenously, fomepizole should be diluted in isotonic saline or dextrose and infused over 30 min. The initial loading dose should be 15 mg/kg, followed by 10 mg/kg every 12 h for four doses, then 15 mg/kg every 12 h, if necessary. During hemodialysis, the frequency of dosing should be increased to every 4 h, whereas every 8 h are likely sufficient during continuous dialysis modalities (CRRT) [62] (Grade III recommendation). Old guidelines have suggested treatment until the blood level of methanol is less than 6 mmol/L (20 mg/dL) and the patient is without symptoms, but increasing this to 10 mmol/L (32 mg/dL) seems reasonable, given no acidosis or end organ toxicity [62].

Ethanol. If ethanol is used to inhibit methanol metabolism, most authors recommend a therapeutic blood ethanol level of about 22 mmol/L (100 mg/dL). However, the amount of ethanol necessary to block methanol metabolism depends on the concomitant methanol level, because there is a dynamic competition for the enzyme alcohol dehydrogenase. If the blood methanol level is known, the molar ethanol concentration should be at least a quarter of the molar methanol concentration [11, 18, 62] (Grade II-2 recommendation).

A dosing suggestion to obtain a blood ethanol level of 22 mmol/L (100 mg/dL) is presented in Table 3 [62]. The maintenance infusion should be increased or decreased according to measured ethanol concentrations. Monitoring the blood ethanol concentration is important yet often not

Table 3 Simplified dosing suggestion for intravenous and oral ethanol treatment^a (Adapted with permission from McMartin KE, Jacobsen D, Hovda KE. Antidotes for poisoning by alcohols that form toxic metabolites [62]).

Intravenous^b	IV 5% ethanol		IV 10% ethanol

^aThese suggestions is based on a paper by from [70] and are only suggestions for the initiation of ethanol treatment. Because of the large interindividual variability in ethanol metabolism, serum ethanol concentrations should be monitored every 1–2 if this is available. Effectiveness of blocking can be monitored by analysis of metabolite concentrations (ideally) or of arterial blood gases, if the metabolite and ethanol analyses are not available

^bEthanol can be very irritating, and IV formulations should be diluted with isotonic 5% glucose (dextrose) to a maximum of 10% ethanol by volume and administered through a central IV line. If ethanol is administered orally, a 20% or more diluted solution is usually better tolerated

^cDialysis (HD) refers to intermittent (high-flow) hemodialysis. During continuous renal replacement therapy (CRRT), the ethanol increase would be smaller than in table, about 20% above the non-dialysis dose is estimated [105]

available [9]. The blood ethanol concentration should be measured every 1–2 h if possible. Hemodialysis removes ethanol. As a rule of thumb, the maintenance dose of ethanol should at least be doubled during hemodialysis (see Table 3) [62].

If a blood methanol concentration cannot readily be obtained, fomepizole or ethanol therapy should be started in any suspected methanol-intoxicated patient with metabolic acidosis, clinical features (dyspnea, visual disturbances), or a history of a potentially toxic ingestion. By consensus, fomepizole or ethanol treatment should be discontinued when the methanol level decreases to less than 6 mmol/L (20 mg/dL). The use of this value has not been empirically validated, however. The lack of reported adverse effects associated with the practice of using the 6 mmol/L (20 mg/dL) value suggests that this practice is safe. It is likely, but unproven, that stopping therapy at higher blood methanol concentrations is

also safe, provided there is no metabolic acidosis. This is particularly true of patients treated with fomepizole, because the inhibition of alcohol dehydrogenase caused by this agent is likely to be effective for more than 12 h after the last dose.

Hemodialysis

Hemodialysis effectively removes methanol and formate and helps to correct the metabolic acidosis [11, 71]. Both intermittent and continuous modalities are frequently used in these patients, but intermittent dialysis is shown to be more effective [17]. Peritoneal dialysis may also remove methanol but not as effectively as hemodialysis [72]. Hemoperfusion is most probably ineffective.

It is difficult to establish strict indications for hemodialysis in methanol poisoning. The only generally accepted absolute indication for hemodialysis is a new visual impairment of any degree in a patient with metabolic acidosis or a detectable

Fig. 6 Healthy male patient admitted after drinking a methanol/ethanol mixture [16]. Note low S-formate and very high S-methanol that was very slowly eliminated during fomepizole treatment (half-life 77 h). Elective hemodialysis was therefore performed (during regular day time) to speed up methanol elimination (half-life during dialysis was 1.7 h). Further course was uneventful (Printed with permission from Hovda et al. [16])

methanol level. Relative indications include severe metabolic acidosis (particularly if unresponsive to bicarbonate and ethanol or fomepizole therapy), a blood methanol concentration greater than 16 mmol/L (50 mg/dL), and ingestion of more than 1 g/kg of methanol. The slow elimination of methanol during ethanol/fomepizole treatment (plasma half-life of 45–80 h) [10, 11, 13] must always be considered when the indication for hemodialysis is discussed. From a practical point of view (drunk patient for days in the intensive care unit), this means that ethanol therapy alone is not acceptable in patients with moderate methanol levels, even if they are admitted early or for some other reasons have little metabolic acidosis (concomitant ethanol ingestion). In some of these patients (e.g., blood methanol 32 mmol/L [100 mg/dL], no visual complaints, and almost normal acid–base status), where fomepizole is the antidote in use, hemodialysis can sometimes be obviated or postponed (Fig. 6) [16, 62, 73–75].

Provided there is no metabolic acidosis or visual disturbances, we recommend that hemodialysis is best continued until the blood methanol level is less than 10 mmol/L (32 mg/dL) and the acidosis is corrected [62] (Grade III evidence). If

methanol analyses are unavailable, we recommend that hemodialysis should be continued for at least 8 h.

Folate/Folinic Acid

The use of folate/folinic acid in methanol poisonings is based on the theory that the endogenous metabolism of formate is folate dependent; thus, a saturation of the metabolizing enzymes occur. A positive effect of adding folate has been shown in animals [19, 76], but no clinical trials have been able to verify an improved outcome [50, 77], partly because of ethical problems designing such a study. However, the benefit of giving this B vitamin is likely to outweigh the risk (few side effects, relatively cheap treatment); hence, a dose of 50 mg four times a day (every 6 h) is recommended (Grade III recommendation).

Criteria for ICU Discharge in Methanol Poisoning

Metabolic acidosis corrected
 Hemodialysis terminated
 Serious acute clinical manifestation resolved

Risk group	Name on figure	Number in total	Dead in group	Total mortality risk	Odds ratio (95% CI) *
1	A and B	206/301	9/206	4%	1
2	C	15/301	3/15	20%	6 (1-23)
3	D	14/301	6/14	43%	16 (5-57)
4	E	24/301	15/24	63%	37 (13-106)
5	F	42/301	35/42	83%	109 (38-313)

*Odds ratio (OR) and 95% confidence intervals (CI) for death for all groups compared to risk

Fig. 7 Risk assessment chart for the evaluation of outcome based on simple admission parameters with a risk score based on the scheme above; pCO₂ values are given in

kPa. Conversion factor mmHg to kPa is 7.5:1. This chart is based on data merged from similar Figures [3, 56]

Prognosis

Unlike with ethylene glycol, a clue about the outcome in methanol poisonings may be found on admission to hospital. Clinical features such as the presence of coma on admission [1–3, 56, 78–80], the degree of metabolic acidosis [1–3,

56, 78–80], and the ability to hyperventilate if a severe metabolic acidosis is present (pCO₂ vs. pH) [1–3, 56] are all strong prognostic markers. Figure 7 illustrates how prognosis can be assessed on admission simply by evaluating the patient’s consciousness and blood gas. In addition, hyperglycemia has been suggested as a

prognostic marker on admission [3, 81], whereas methanol concentration itself has no prognostic value [1, 2, 56].

As for the long-term prognosis, visual disturbances and brain damage were found to persist or get worse 6 years after discharge in a follow-up study from Estonia [82]. Similarly, Zakharov et al. found the prevalence of long-term visual sequelae to be significantly higher than the visual sequelae on discharge (also in comparison to the literature), suggesting that the morbidity from these poisonings is an underreported feature: At least 22% of the patients without subjective complaints of visual disturbances that were discharged from hospital without detected visual damage had abnormal findings using advanced examination on follow-up [83].

Other

Consultation with a poison center or clinical toxicologist is strongly recommended if the treating physician is unfamiliar with the management of methanol poisoning. In addition, physicians who do not know how to obtain either methanol or formate blood levels may be able to obtain such information from these sources. When the diagnosis of methanol poisoning is made or suspected and hemodialysis is contemplated, a nephrologist should be consulted, especially when the patient is admitted in a late stage or after large ingestions.

All patients with suspected methanol poisoning for whom a serum methanol concentration is unavailable should be observed for continued clinical and laboratory evaluation: If an ethanol level is available, a patient suspected of drinking methanol recently should be monitored using blood gases for at least 6 h after the ethanol level is zero, based on the time needed for a detectable acidosis to develop after the antidote is eliminated. If formate analyses are available, they will be able to detect small levels of formate hours before the patient even have symptoms (see Fig. 3) [39]. Every patient with a definite diagnosis of methanol intoxication should be admitted and have an initial and follow-up examination by

an ophthalmologist as the incident may have legal and insurance implications [83].

If hemodialysis is unavailable, the patient who needs it, or will probably need it, should be transferred to a facility with this capability, and fomepizole or ethanol should be given immediately [63]. Alkali treatment should be provided if any indication of a metabolic acidosis is present. These treatments should be continued during transport. Because plasma ethanol concentrations should be monitored every 1–2 h due to the difficulty of keeping a constant ethanol level, fomepizole is the preferred agent for transfers that may last more than 1 h [62].

Special Populations

When treating a methanol-poisoned patient, it must always be borne in mind that other people may also have ingested the illicit spirit (containing methanol), believing it was ethanol. If so, these victims must be traced [7, 9] and evaluated in an emergency department.

Some patients presenting with coma (GCS 3) and extreme metabolic acidosis (e.g., pH 6.60, $p\text{CO}_2$ 1.4 kPa, BD 28 mmol/L, HCO_3^- 1 mmol/L) may not survive because of brain edema leading to “brain death.” It is, however, important to consider further optimal treatment and possible organ donation as the biochemical disturbances in other organs can often be reversed. In our experience such “hopeless cases” have been donor to up to six recipients – as also experienced by others [84–88].

Common Errors in Methanol Poisoning

Delayed diagnosis because of failure to consider methanol poisoning in the differential diagnosis of metabolic acidosis of unknown origin

Failure to consider that there may be multiple victims when the source of methanol is unknown or is known to be a contaminated ethanol beverage

(continued)

Failure to appreciate that the absence of early symptoms and the presence of normal anion or osmolal gaps do not exclude a potentially toxic methanol ingestion

Failure to observe all patients with known or suspected methanol ingestion until a methanol level can be obtained

Failure to give enough ethanol during hemodialysis because ethanol is removed as well

Failure to have visual function formally assessed by an ophthalmologist in patients with methanol poisoning

Formaldehyde

Formaldehyde, the one-carbon aldehyde (HCHO), exists in the gaseous state as a reactive chemical with a distinctive disagreeable odor. The odor is sufficient to provoke flight responses in that humans cannot remain in intolerable atmospheres [89]. The most common liquid form of formaldehyde is formalin, which usually contains 37% formaldehyde in water by weight, along with methanol in concentrations of 15% as a stabilizing agent (preventing polymerization). Cases of oral ingestion of formaldehyde (mostly formalin solutions) have been reported [90–95], albeit rarely because of the disagreeable nature of the solution.

Formalin is used as a disinfectant, tissue preservative, and embalming solution; occupational exposure generally involves inhalation or skin contact. Formaldehyde vapor is irritating to mucosal membranes and has caused problems in occupational settings where the concentrations reach levels of 1 ppm [96]. Formaldehyde is also present in resins, insulation, plywood, and textiles, such that it also has been found in the indoor air of residential and business areas, particularly where urea-formaldehyde resins are used in insulation or furnishings. Regarding such low level exposures, the US National Toxicology Program and the International Agency for Research on Cancer have classified formaldehyde as a human carcinogen [89, 97, 98].

Pathophysiology

Formaldehyde reacts readily and covalently with amine groups such as those found in proteins and nucleic acids. Animal studies have confirmed that formaldehyde produces protein–DNA cross-links [99]. Such covalent adducts or cross-links would produce a loss of protein or nucleic acid function, which is a potential mechanism by which toxicity could be produced.

Formaldehyde is highly irritating to mucosal tissues, such as the eyes, nose, and respiratory tract, either by direct caustic reaction or through covalent interactions. These reactions include tearing, coughing, sneezing, and sometimes bronchospasm. Formaldehyde also reduces mucociliary clearance activity [89] and may affect lower respiratory tissue if attached to particulates. Formaldehyde may provoke allergic responses, including contact dermatitis and asthmatic reactions [100].

Ingested formaldehyde is apparently absorbed rapidly into the bloodstream [90]. It is then rapidly degraded in the tissues by metabolism to formic acid, primarily through the enzyme formaldehyde dehydrogenase [101]. This enzyme catalyzes the reaction of glutathione, formaldehyde, and nicotinamide–adenine dinucleotide to yield S-formylglutathionine, which is hydrolyzed to formate and reduced glutathione by S-formylglutathionine hydrolase. These activities are widely expressed in all human tissues, although the highest activity is in the liver. Formaldehyde also can be oxidized to formate by a nonspecific aldehyde dehydrogenase and by the folate-dependent, one-carbon metabolic system [38].

Because of the widespread metabolism, formaldehyde is eliminated extremely rapidly from the blood, with a half-life of 1–2 min [102]. Several studies in animals and one case report have indicated that systemic formaldehyde is completely converted to formic acid within a relatively short time [90, 103, 104]. Formaldehyde is metabolized to carbon dioxide (via oxidation of formate), although a small amount is incorporated into macromolecules via folate-dependent pathways or direct interaction of formaldehyde

with amine groups. The systemic toxicity of formaldehyde primarily results from the accumulation of formic acid and the ensuing metabolic acidosis [90].

Clinical Presentation

Several case reports of formalin ingestion have provided a general clinical picture. Ingestion of 45 mL of the typical 37% solution [92] has produced gastrointestinal ulceration with little systemic toxicity, whereas massive systemic toxicity and lethality were observed after consumption of 120 mL [90]. Ingestion of formalin often produces immediate vomiting and severe abdominal pain. Ulceration of the oropharynx, esophagus, and stomach is widespread. The duodenum appears less affected and often normal. In one patient who survived, these lesions did regress over 4 weeks, although there was some residual scarring of the distal body and antrum [92].

Respiration becomes labored, with shortness of breath. Metabolic acidosis, with pH of 6.9, is reported [90, 94]. Chest radiographs show pleural effusions and infiltrates. Muscle spasm and the body may become stiff and rigid. There is laboratory evidence of rhabdomyolysis [94].

Formaldehyde causes weakness leading to stupor and coma. Hypotension and shock follow as the gastrointestinal damage and acidosis worsen. Ventricular tachycardia has been reported. Eventually anuria ensues, indicating development of renal failure. Death due to the failure of multiple organ systems can occur within 24 h [90].

Dialysis systems contaminated with formaldehyde have been associated with the occurrence of hemolysis [104] in patients. Chronic exposure to formaldehyde may therefore cause hemolytic anemia. Although significant formate accumulation seems to occur in patients with formaldehyde exposure, minimal ocular toxicity seems to be present. A patient with formaldehyde poisoning and metabolic acidosis should have vision checked, however, as noted earlier under methanol poisoning.

Diagnostic Considerations

A positive exposure history is the initial key to diagnosis. In a patient without confirmed ingestion, several features aid in the diagnosis. First, the odor of formaldehyde should be observed on the breath. On lavage in one patient, this odor was noted strongly in the gastric contents [90, 94]. Two indicators of potential formaldehyde exposure are the presence of severe lesions of the gastrointestinal tract, especially in the oropharynx, and a severe, systemic metabolic acidosis (a decreased arterial blood pH, an increased anion gap, or a decreased serum bicarbonate concentration). Because these indicators are not definitive, an accompanying increase in blood formate concentrations would suggest that there had been an ingestion of methanol, formic acid, or formaldehyde. Although the laboratory measurement of blood formate concentrations is rarely available, the treatment for either ingestion should be the same.

Treatment

Because of the potential for massive multiorgan damage, aggressive supportive care needs to be instituted rapidly [90, 94]. Rapid intubation and ventilatory support should be instituted for standard indications. Gastric lavage with saline or bicarbonate solutions, even if applied within 1–3 h of ingestion, is probably of little value because of the potential for further corrosive damage. If there is little corrosive damage to the esophagus, the benefit of decontamination must be weighed against the risk. The possibility of corrosive injury and the unlikely efficacy of the procedure suggest, however, that lavage should not be performed. Intravenous fluids help maintain cardiovascular and renal function. If necessary, vasopressors should be given to maintain blood pressure.

The mainstay of treatment beyond supportive care should be to aggressively counteract the systemic accumulation of formic acid. Initially, this counteraction should include intravenous administration of sodium bicarbonate to combat the acidosis [90, 94]. This may also increase the

renal elimination of formate (see above; Methanol Biochemistry and Clinical Pharmacology) [13]. Although never attempted in previous cases, administration of folate or folinic acid, as detailed earlier, should increase the metabolic elimination of formate. Hemodialysis should be initiated as soon as possible. Although not formally studied, it seems logical that the indications for hemodialysis are similar to those enumerated for methanol. In one patient who had consumed a lethal amount of formaldehyde and was nearly moribund, hemodialysis was started within 6 h of ingestion [94]. The patient improved rapidly, the acidosis was reversed by the end of dialysis, and the patient recovered completely.

Chlorophenoxy herbicides (phenoxy-carboxylic acid herbicides) are weed killers that act as synthetic auxins (plant “hormones”) and cause plant death by disrupting nutrient transport and growth. They are used widely for the control of broad-leaved weeds in pastures and cereal crops and along public rights of way. Chlorophenoxy herbicides are of limited persistence in the environment. They are occasionally coformulated with a hydroxybenzonitrile herbicide such as ioxynil or bromoxynil which is more toxic than a chlorophenoxy herbicide but are added to broaden the spectrum of herbicidal activity.

Chlorophenoxy herbicide poisoning is uncommon in developed countries but reported quite frequently in the developing world. For example, 181 patients presented with MCPA poisoning to just three hospitals in Sri Lanka between April 2002 and October 2003 [1]; eight patients in this series died.

Biochemistry and Clinical Pharmacology**Biochemistry**

Structurally, chlorophenoxy herbicides comprise an aliphatic carboxylic acid moiety attached to a chlorine-substituted or methyl-substituted aromatic ring. The most common herbicide of this class is 2,4-D [(2,4-dichlorophenoxy)acetic acid]; its structural formula and that of related

compounds are shown in Fig. 1. Mecoprop-P is the stereoisomer of mecoprop (the racemate) and dichlorprop-P is the stereoisomer of dichlorprop. 2,4,5-Trichlorophenoxy acetic acid (2,4,5-T) has been largely withdrawn from use due to concerns that some formulations were contaminated with dioxin. Chlorophenoxy herbicides typically are formulated in commercial preparations as salts or esters, for example, the dimethylamine salt of 2,4-D.

Toxicokinetics

Chlorophenoxy compounds are absorbed rapidly after oral administration in humans [2, 3], but dermal [3, 4] and inhalational [5] absorption is limited. When absorbed, the salts or esters of these herbicides dissociate or hydrolyze rapidly. The free acid binds to serum albumin; increased length of the acid chain, and increased substitution of the aromatic ring favor binding. Chlorophenoxy herbicides have relatively low volumes of distribution (approximately 0.1 L/kg for 2,4-D in humans) [6]. However, distribution is affected not only by the extent of protein binding, which is saturable, but also by the extent of herbicide ionization. Because chlorophenoxy herbicides are acids (the pK_a of 2,4-D is 2.73), at physiological pH only a small percentage is in the non-ionized form and available to penetrate lipid membranes.

2,4-D undergoes little metabolic transformation in humans; the free acid is excreted predominantly unchanged in urine [2] with small amounts as a 2,4-D conjugate. Limited experimental data suggest a similar process for other chlorophenoxy herbicides [3]. Active renal tubular secretion has been shown as a primary mechanism of renal clearance in animals [3] though this is saturable at high doses. The elimination half-life of 2,4-D in humans is of the order of 20–30 h [2, 3].

Pathophysiology of Toxic Effects

Chlorophenoxy-induced dose-dependent cell membrane damage [7] is likely to be important in the mediation of central nervous system

Clomeprop [(RS)-2-(2,4-dichloro-*m*-tolylxy)propionanilide]

2,4-D [(2,4-dichlorophenoxy)acetic acid]

2,4-DB [4-(2,4-dichlorophenoxy)butyric acid]

Dichlorprop [(RS)-2-(2,4-dichlorophenoxy)propionic acid]

Dichlorprop-P [(2R)-2-(2,4-dichlorophenoxy)propionic acid]

MCPA [4-chloro-*o*-tolylxyacetic acid]

MCPB [4-(4-chloro-*o*-tolylxy)butyric acid]

Mecoprop [(RS)-2-(4-chloro-*o*-tolylxy)propionic acid]

Mecoprop-P [(R)-2-(4-chloro-*o*-tolylxy)propionic acid]

Fig. 1 Chemical structures of the chlorophenoxy herbicides

Fig. 3 Biosynthesis of 2,4-D-choline

toxicity both by damaging the blood–brain barrier [8] and by disrupting neuronal membrane transport mechanisms [9]. In addition, chlorophenoxy herbicides are related structurally to acetic acid and are able to form analogues of acetyl coenzyme A, such as 2,4-D-CoA [Fig. 2] which in turn can enter the acetylcholine synthetic pathway with the subsequent formation of choline esters such as 2,4-D-choline, which may act as false neurotransmitters at muscarinic and nicotinic synapses [10, 11] (Fig. 3).

Uncoupling of oxidative phosphorylation within mitochondria may result both from damage to intracellular membranes [12] and/or to impaired acetyl-coA metabolism. A variety of cellular activities may be compromised by subsequent adenosine triphosphate (ATP) depletion,

including ATP-dependent ion pumps, DNA and protein synthesis, and processes involved in the maintenance of cell shape.

Commercial preparations contain a variety of other ingredients including solvents, surfactants, sodium and potassium hydroxide, iron, cresols, and phenols that may contribute to the toxicity of the final product [13].

Clinical Presentation and Life-Threatening Complications

Most cases of serious poisoning involve deliberate ingestion of 2,4-D alone, in combination with other chlorophenoxy herbicides or in combination with ioxynil or bromoxynil. However, there were

eight fatalities (4.4%) in a series of 181 patients exposed to MCPA in Sri Lanka that could not be satisfactorily explained in terms of pathophysiological mechanism; the features in 154 of the 181 patients were minimal [1]. We have reviewed previously the toxicity of chlorophenoxy herbicides [14].

Ingestion

Vomiting is a prominent early feature of chlorophenoxy herbicide ingestion [1, 15–17] and may be accompanied by burning or ulceration in the mouth [15], abdominal pain, and diarrhea [1, 15]. Severe corrosive effects, including gastrointestinal hemorrhage, are rare and may be due to other ingredients in some formulations, such as sodium and potassium hydroxide, surfactants, iron, cresols, and phenols. Gastrointestinal fluid loss, vasodilation, and direct myocardial toxicity contribute to hypotension [1, 15, 17, 18], which may precipitate renal failure.

Rapid onset of coma is common in severe cases and may be preceded by a period of agitation and confusion. Coma is almost invariably in patients who die and often lasts several days in patients who survive [15, 17–20]. The incidence of other neurological features varies widely. Hypertonia, hyperreflexia, clonus, and occasionally extensor plantar responses suggest upper motor neuron involvement [21]. Miosis, nystagmus, ataxia, hallucinations, and convulsions also have been reported.

Coma is associated frequently with inadequate ventilation [1, 15, 17–20, 22]. Aspiration of gastric contents may contribute to pulmonary complications. Hemoptysis and pulmonary edema may occur. Hypoventilation secondary to central nervous system depression is the primary cause of hypoxia, although respiratory muscle weakness also may occur as part of a generalized myopathy. In such cases, there may be limb weakness or reduced or absent tendon reflexes and increased creatine kinase activity. Fasciculation and/or myotonia may also be present. Neuromuscular effects may persist for several weeks. A syndrome similar

to Guillan Barré has been described in a patient who survived severe poisoning with a mixture of MCPA, 2,4-D and MCPP [23]. Electromyography evidence of a peripheral neuropathy has been reported rarely [20, 24].

Metabolic complications include acidosis, hyperthermia in the absence of infection (possibly reflecting uncoupling of oxidative phosphorylation), and rhabdomyolysis. The latter may contribute to increased aspartate and alanine aminotransferase activities. Thrombocytopenia, hemolytic anemia, and hypocalcemia are recognized rarely.

The prognosis is poor in patients who rapidly become shocked and comatose but cases of delayed (>8 h post ingestion) sudden deterioration have also been reported. For example, respiratory distress, hyperthermia, hypotension, and metabolic acidosis escalated in one case between 8 and 20 h post ingestion, cumulating in a fatal cardiac arrest despite full ICU support including mechanical ventilation, vasopressors, and continuous veno-venous hemodialysis [25]. Conversely, full recovery can ensue over weeks to months despite initial severe toxicity.

Inhalational and Dermal Exposure

Because dermal and inhalational absorption of chlorophenoxy herbicides is poor, acute poisoning via these routes is uncommon. Local irritation to the skin and mucous membranes may occur, but there are very few reports of systemic toxicity after such exposures. Interpretation of cases in which systemic effects are described is complicated, and the etiologic role of chlorophenoxy herbicides in many has been challenged [26]. Reported features include mild-to-moderate gastrointestinal symptoms followed by variable manifestations of peripheral neuropathy or myopathy [27–33]. Despite widespread use, there have been no published reports of systemic chlorophenoxy herbicide poisoning after dermal or inhalational exposure since at least the 1980s and no reported fatalities from such exposures.

Diagnosis

There should be no diagnostic difficulty when a history of deliberate chlorophenoxy herbicide ingestion is forthcoming, but familiarity with the clinical presentation may hasten diagnosis when self-harm is suspected but no history is available. The presence of muscle fasciculation, weakness, and/or myotonia may result in misdiagnosis of organophosphorus insecticide poisoning. The toxicological differential diagnosis also includes poisoning by salicylates or psychotropic drugs. Measurement of plasma chlorophenoxy herbicide concentrations may be undertaken for diagnostic confirmation [34], although these assays are not widely available. There is no definite relationship between total plasma chlorophenoxy herbicide concentrations and severity of poisoning, although Flanagan and colleagues [15] suggested that a total plasma chlorophenoxy herbicide concentration greater than 500 mg/L is associated with severe toxicity.

Treatment

Initial assessment and treatment of patients exposed to chlorophenoxy herbicides should follow generally accepted guidelines of current practice for external and gastrointestinal decontamination and supportive care. In vitro studies showed that chlorophenoxy herbicides are adsorbed to activated charcoal [35]. The administration of oral activated charcoal, 50–100 g in an adult, may be considered reasonable in patients who have ingested a potentially toxic amount of a chlorophenoxy herbicide within 1 h. Activated charcoal therapy has not been shown, however, to affect the outcome of chlorophenoxy herbicide-poisoned patients. Although most patients can be managed with symptomatic and supportive care alone, controversy surrounds the use of urine alkalization, hemodialysis, and hemoperfusion in enhancing herbicide elimination in severely poisoned patients.

Urine Alkalinization

No controlled trials of urine alkalization have been carried out in chlorophenoxy herbicide poisoning. Despite several case reports claiming enhanced elimination with urine alkalization [15, 16], there are sufficient data to examine this claim only for one patient [20, 36]. The patient, a 39-year-old man, developed features of severe poisoning after the ingestion of a calculated 6.8 g of 2,4-D and 13.6 g of mecoprop. The admission urine pH was 6.4, and the plasma 2,4-D concentration was 400 mg/L. An “alkaline diuresis” comprising 14 L of fluid containing 69.3 g of sodium bicarbonate (825 mmol) over 48 h [20] was instituted approximately 42 h post ingestion, but a urine pH greater than 7.5 was not achieved until 70–75 h post ingestion.

The renal 2,4-D clearance corrected to a urine flow of 1 mL/min was related directly to urine pH ($r = 0.99$) and was estimated to increase almost fivefold for each unit increase in urine pH. The mean corrected 2,4-D renal clearance was 0.28 mL/min over the urine pH range 5.1–6.5 and 9.6 mL/min over the urine pH range 7.55–8.8 (Table 1) [36]. At pH 5.1 and 8.3, the *uncorrected* 2,4-D renal clearances were 0.14 mL/min and 63 mL/min. The plasma half-life of 2,4-D decreased from approximately 219 h before alkaline diuresis to 3.7 h at 96–112 h postingestion when the urine pH exceeded 8.0 [20], and the amount recovered in the urine was 6.66 g.

The renal mecoprop clearance corrected for a urine flow rate of 1 mL/min also was related directly to urine pH ($r = 0.94$). It approximately doubled with each unit increase in urine pH [20] from 0.38 mL/min over the urine pH range 5.1–6.5 to 2.08 mL/min over the urine pH range 7.55–8.8 (see Table 1). The plasma half-life of mecoprop was shortened from 39–14 h, and the amount recovered in the urine was 7.64 g [20]. Clinical improvement paralleled the decrease in 2,4-D and mecoprop concentrations, and consciousness was regained on the fourth day after ingestion, when the plasma 2,4-D and mecoprop concentrations were approximately 100 mg/L.

The uncorrected renal 2,4-D clearance (0.14 mL/min at urine pH 5.1) determined by

Table 1 Effect of urine alkalization on plasma half-life and mean corrected (to 1 mL/min urine flow) renal clearance of 2,4-D and mecoprop

Urine pH (range)	2,4-D		Mecoprop	
	Clearance (mL/min)	Half-life (hr)	Clearance (mL/min)	Half-life (hr)
5.10–6.5	0.28	219	0.38	39
6.55–7.5	1.14	42	0.65	22
7.55–8.8	9.60	4.7	2.08	14

Adapted from Park et al. [36]

Prescott and coworkers [20] was similar to that found previously (0.17–1.4 mL/min) [37]. A high 2,4-D renal clearance was achieved, however, only when the urine pH was greater than 7.5 and urine flow was greater than 200 mL/h. The maximum uncorrected 2,4-D renal clearance of 63 mL/min at pH 8.3 [20] would have required a urine flow rate of approximately 600 mL/h and compared favorably with that achieved with hemodialysis (56.3–72.9 mL/min) [19]. However, the *corrected* renal clearance data show that urine alkalization without high urine flow is markedly less efficient than hemodialysis as a means of removing 2,4-D.

The less beneficial effect of urine alkalization on mecoprop clearance compared with 2,4-D clearance may be explained by the much greater clearance of mecoprop by metabolism and the fact that mecoprop is a weaker organic acid (pK_a of 3.78 and 2.73). Renal mecoprop clearance would be less affected by changes in urine pH.

A Cochrane review of the role of urine alkalization for acute chlorophenoxy poisoning concluded in 2007 [38], “it is not unreasonable to attempt urinary alkalization. . . given that toxicity may be prolonged and result in death after 24 h, few significant adverse effects have been reported from urinary alkalization, and the potential for this treatment to provide some benefit.” The level of evidence for recommendation of urinary alkalization is thus Level III.

Hemoperfusion and Hemodialysis

Durakovic and associates [19] treated four patients with 2,4-D poisoning by hemodialysis,

though clearance data was only available in three cases and in two cases; resin hemoperfusion also was instituted. The dialysis clearance in one patient was 68.7 mL/min, and in the two patients receiving combined therapy, the clearances were 56.3 mL/min and 72.9 mL/min. Urine alkalization combined with a high urine flow (600 mL/h) produced similar clearance values [20, 36]. Several other authors [39, 40] have described a favorable outcome in patients with severe poisoning following ingestion of chlorophenoxy herbicide-containing formulations treated with hemodialysis, without giving clearance values, though apparent failures of extracorporeal elimination therapies have also been described [41].

The reported clearances of 2,4-D during hemodialysis alone or combined with hemoperfusion were relatively unimpressive and were similar to those reported with high-flow urine alkalization. Nonetheless, in cases of severe 2,4-D poisoning, hemodialysis should be considered, particularly if high-flow urine alkalization cannot be performed for clinical reasons. The level of evidence for this recommendation is Level III.

Indications for ICU Admission in Pesticide Poisoning

History of substantial ingestion in preceding 8 h, regardless of symptoms
Severe vomiting and/or diarrhea
Hypotension unresponsive to fluid resuscitation
Central neurological or neuromuscular symptoms or signs

Criteria for ICU Discharge

Resolution of severe vomiting and diarrhea without new features
 Resolution of hypotension, without new features
 Resolution of, or substantial improvement in, central neurological or neuromuscular symptoms or signs

Common Errors in Management

Failure to consider the potential contribution to the clinical picture of solvents and adjuvants in the formulation
 Presence of muscle twitching, fasciculation, and weakness leading to a misdiagnosis of organophosphorus insecticide poisoning
 Inadequate monitoring and clinical review in first few hours after a substantial ingestion
 Assumption that pyrexia must be due to infection when other metabolic explanations are possible

Key Points

1. Severe poisoning is likely only after ingestion.
2. The level of consciousness may deteriorate rapidly after substantial ingestion.
3. Neuromuscular effects may persist for several weeks.

Fumigants are nonspecific pesticides that exist as gases or vapors or are capable of being changed to one of these states. They represent a diverse group of compounds (Table 1) that are dissimilar in their chemical structures, physical properties (Table 2), and mechanisms of injury. This broad category of substances includes liquids (ethylene dibromide, dibromochloropropane, formaldehyde) that can vaporize, solids that may release toxic gases when mixed with water (zinc phosphide, aluminum phosphide), cyanide salts (sodium or calcium cyanide) that liberate hydrogen cyanide gas when acidified, and gases (methyl bromide, hydrogen cyanide, ethylene oxide). Fumigants are used to control pests in confined, enclosed, or sealed environments. Examples of typical fumigant targets are rodents or insects in stored grain products, wood-destroying insects such as dry-wood termites or wood beetles, and nematodes and fungi in the soil that adversely affect crop production. Examples of specific confined areas are railroad hopper cars, silos, and storage areas. Cyanide is discussed in its own chapter and is not addressed here.

Fumigant gases or vapors are intended to dissipate after the enclosed space has been opened and ventilated. For organisms living within that enclosed space, the fumigants are indiscriminate poisons. They affect targeted pests and other organisms that may not be an intended target, including workers that may enter the treated area unknowingly. Therefore, treated areas should

This chapter is largely based on the chapter by Scott D. Phillips in the first edition of this book.

Table 1 Names and common uses of selected fumigants

Common name	Synonyms	Uses
Methyl bromide	Bromomethane, monobromomethane, embafume	Pesticide fumigant for soil, mills, warehouses, vaults, ships, freight cars, etc. Wool degreaser
Sulfuryl fluoride	Sulfur difluoride dioxide, vikane	Pesticidal fumigant, especially for structures with dry-wood termites or wood beetles
Chloropicrin	Trichloronitromethane, nitrochloroform, larvacide, picfume	Pesticidal fumigant for soil, cereals, and grains; chemical synthesis; military "tear gas"
Aluminum phosphide	Celphos, detia, phostoxin	Pesticidal fumigant, especially for animal feed, bulk grain, cottonseed, leaf tobacco, and flour mills; phosphine source, semiconductor industry
Zinc phosphide	ZP	Rodenticidal fumigant
Carbon disulfide	Serafume, vertifume	Pesticide, manufacturing
Chlorine dioxide	Alcide, doxide 50	Fumigant, algicide
Acrylonitrile	Acrylon, carbacryl, aculofume	Pesticides, semiconductor industry

Table 2 Properties of selected fumigants

Chemical	State	Color	Odor/irritation	Water Solubility (% g/dL)	Boiling Point (°F)	Vapor Pressure (mm Hg)	IDLH (ppm)
Methyl bromide	Gas	Colorless	Odorless	2%	38	1.9	250
Sulfuryl fluoride	Gas	Colorless	Odorless	0.2%	−68	15.8	200
Chlorine dioxide	Gas	Yellow	Acidic	3%	51.8	760	5
Carbon disulfide	Liquid	Colorless to yellow	Sweet aromatic	0.08%	114.8	359	500
Chloropicrin	Liquid	Colorless to yellow	Intensely irritating	0.2%	234	18	2
Aluminum phosphide	Solid	Dark gray or yellow	Fishy	NA	NR	NR	NR
Zinc phosphide	Solid	Dark gray	Phosphorus-like	NA	2012	NR	NR
Acrylonitrile	Liquid	Pale yellow	Slight peach	7.2%	171.1	100	85
Ethylene dibromide	Liquid	Colorless	Sweet chloroform	0.4%	267.8	11.25	100

NR not reported, NA not applicable, IDLH immediately dangerous to life and health

have warning signs (placarding) indicating the date and time of safe entry.

Methyl bromide and sulfuryl fluoride are prototypic fumigants. They are gases at room temperature and 1 atm pressure, are poorly water soluble, are odorless, and are not significantly

irritating to the mucous membranes. Because many fumigants have poor warning properties, chloropicrin (CCl_3NO_2) often is added as a warning agent. Chloropicrin is intensely irritating to all mucous membranes and has been used as an incapacitating lacrimator in military poison gases.

The specific mechanisms of action, including specific molecular targets, have not been elucidated in detail for many of the fumigants. The clinical signs and symptoms of poisoning by these compounds are well known, but for many their effects at the cellular and molecular levels still are being explored.

Phosphides

Aluminum phosphide (AlP) and zinc phosphide (Zn_2P_3) are solids and usually formulated as pellets or encased in packets. When either phosphide reacts with water or acid, phosphine gas (PH_3), the fumigant, is liberated. All typical routes of exposure may occur with fumigants, although inhalation is the most likely in the USA. In India, ingestion of fumigant pellets has become an important source of morbidity and mortality [1].

There is experimental evidence that phosphine noncompetitively inhibits mitochondrial cytochrome oxidase, interfering with cellular respiration and adenosine triphosphate formation [2]. Methemoglobinemia has also been described [3]. Myocardial cells are particularly sensitive to this noncompetitive inhibition of cytochrome oxidase [4]. Phosphine interferes with incorporation of amino acids into myocardial proteins, which can result in heart failure [4]. In the lung, phosphine directly damages the alveolar-capillary membrane, potentially resulting in the acute respiratory distress syndrome and hypoxemia. Phosphine is a small peripheral arteriole vasodilator that may cause decreased systemic vascular resistance, with possible hypotension, and distributive shock [5]. Spontaneous self-ignition due to phosphine has been described more than once [6, 7].

In a series of grain storage workers acute inhalational exposure to aluminum phosphide was reported to cause cough, dyspnea, chest tightness, headache, numbness, lethargy, and epigastric pain [8]. In a report of eight intentional aluminum phosphide ingestions, the same investigators described gastritis, altered sensorium, distributive shock, renal failure, and cardiac arrhythmias. Six patients died. Postmortem findings included pulmonary edema, intestinal edema, petechial

hemorrhages on the liver and brain, and desquamation of the epithelial lining of the bronchioles [9].

The diagnosis of phosphide poisonings is usually based on known exposure and the clinical presentation. While aluminum and zinc levels may be obtained, they are not required for either the diagnosis or prognosis. Phosphide in gastric contents can be confirmed via the silver nitrate test, whereby gastric aspirate is heated to 50 °C in a flask and the resulting vapor leads to blackening of silver nitrate impregnated filter paper [10].

Zinc is electron dense and presence of radio-opaque foreign bodies in a known exposure can suggest clinically significant exposure in initially asymptomatic patients [11]. Phosphide poisoning is discussed in greater detail in its own chapter.

Methyl Bromide

Methyl bromide (CH_3Br) is colorless, odorless, and three times as heavy as air. The latter attribute is important in that this gas, and others that are heavier than air, collect in low-lying places. This property is beneficial for fumigation but is potentially responsible for unintended exposures. By cooperative agreement, methyl bromide was phased out of use by 2005 in industrialized nations.

Methyl bromide typically is used as a soil fumigant. It also has been used to treat stored fruit in ship holds or in special fumigation chambers in aircraft. Nonfumigant uses of methyl bromide include use as a methylating agent, refrigerant, and fire retardant. The main routes of exposure to humans are inhalation and skin contact.

Methyl bromide is a potent alkylating agent with high affinity for sulfhydryl and amino groups. It binds to amine groups in amino acids, interfering with protein synthesis and function [12]. Sulfhydryl-containing amino acids and proteins can be damaged at their amino and sulfhydryl sites. Given that methyl bromide is an alkylating agent, it may methylate many other cellular components, including glutathione, proteins, DNA, and RNA [12].

Because of methyl bromide's lack of warning properties, the unwary worker may come into contact with dangerous concentrations of this gas unknowingly [13]. Symptoms may evolve over hours. Initially, mild symptoms, such as headache and eye, nose, and sinus irritation may be reported [14]. At higher concentrations, central nervous system (CNS) and respiratory complaints predominate [15, 16]. CNS complaints may include seizures, myoclonus, tremors, peripheral neuropathy, ataxia, vertigo, respiratory paralysis, coma, and cerebral edema [17, 18]. Respiratory tract irritation, burns, pulmonary edema, and ultimately ventilatory failure may occur [16, 19]. Skin irritation and burns may occur after large exposures [20]. The typical lesions are blisters with surrounding erythema [21]. Eye injuries may occur, with severe inflammation leading to temporary blindness [22]. Patients should have prompt skin and eye irrigation if indicated.

Methyl bromide exposure has been associated with increased incidence of stomach cancer in agricultural workers [23].

Sulfuryl Fluoride

Sulfuryl fluoride (SO_2F_2) is odorless and colorless. The exact mechanism of action of sulfuryl fluoride is unknown. Its vapor pressure is similar to water. The respiratory system, CNS, and cardiovascular system are the primary target organ systems [24]. Free fluoride anion is released soon after contact [24]. At autopsy, markedly elevated fluoride concentrations have been found in the heart blood of one of two sulfuryl fluoride poisoning victims. The blood fluoride concentration obtained 6 days after exposure was 0.5 mg/L [25]. When sulfuryl fluoride is combusted in the presence of water vapor, it may form acidic vapors, such as hydrofluoric acid. The latter is discussed in greater detail in its own chapter.

Fluoride combines with divalent cations, primarily calcium and magnesium, potentially resulting in hypocalcemia, hypomagnesemia, and hyperkalemia from cellular destruction [26]. This constellation of electrolyte abnormalities can manifest as CNS irritability with agitation, tetany, or seizures [26]. These electrolyte abnormalities

also may cause prolongation of the QT interval, torsades de pointes, bradydysrhythmias, wide QRS complexes, or asystole [27]. Acute bronchospasm has been reported after sulfuryl fluoride inhalation [28]. Limited exposures may cause nausea, vomiting, and diarrhea [28].

In one case report, a woman developed burning to her eyes, abdominal pain, hypotension, and convulsions, followed by torsade de pointes, ventricular fibrillation, and asystole despite aggressive treatment with endotracheal intubation, 7 gm of calcium salts, 6 gm of magnesium, 2 mg of epinephrine, 2 ampules of sodium bicarbonate, 1 mg of atropine, and fluids [29]. While supportive care with electrolyte monitoring and airway support are recommended, it is unclear whether such interventions have any effect on morbidity and mortality.

Chloropicrin

Chloropicrin is a lacrimator and a pulmonary irritant. It is a colorless-to-yellow liquid with a sweet, slightly aromatic odor. It is one of the more volatile fumigants. Chloropicrin is highly irritating to all mucous membranes and was used in World War I as a tear gas because of its strong lacrimating properties [28, 30]. Chloropicrin's mechanism of action has not been elucidated fully. It is slightly water soluble, intermediate between chlorine gas and phosgene gas, and its effects are similar to these gases [31]. Chloropicrin is corrosive with local toxic effects on exposed mucous membranes, the respiratory tract including the alveolar-capillary membrane, and the eyes [32]. Common clinical findings in patients after exposure to chloropicrin vapors include cough, erythema, tearing, rhinorrhea, headache, and irritation [14, 33]. After ingestion, irritation of the gastrointestinal tract would be expected due to the corrosive nature of this substance.

Ethylene Dibromide

Ethylene dibromide ($\text{CH}_2\text{BrCH}_2\text{Br}$) is a colorless substance, also referred to as 1,2-dibromoethane. Ethylene dibromide first found use in 1948; its biocidal properties led to its use as a soil sterilant.

In addition to its use as a fumigant, it was employed as an antiknocking agent in gasoline. In contrast to many other fumigants, ethylene dibromide is a dense liquid, and it has a sweet odor. The vapor pressure is approximately that of water, and poisoning typically occurs from direct contact. Of note, it is able to penetrate protective clothing, including neoprene and rubber [20].

Patients exposed to ethylene dibromide may have mucous membrane irritation, skin irritation and blistering, and respiratory distress [34–36]. Cardiac effects including bundle-branch blocks, supraventricular tachycardia, ventricular fibrillation, and asystole have been described [34–36]. In cases of severe intoxication, hypotension and shock may occur [35–37]. Hepatic failure and renal insufficiency have been reported after significant exposure to ethylene dibromide [38]. Pathology of ethylene dibromide-related liver injury is characterized as centrolobular necrosis [34]. Ethylene dibromide has weak anesthetic properties that may result in CNS depression and ultimately coma at high doses [34, 35, 39].

Ethylene dibromide is converted by hepatic microsomal cytochrome P-450 isozymes (CYP2E1, CYP2A6, CYP2B6) and cytosolic glutathione-S-transferase isozymes (A1-1, A2-2, M1a-1a, P1-1) in vitro to bromoacetaldehyde, bromoacetic acid, thiodiacetic acid, S-2-bromoethylglutathione, and S-(2-hydroxyethyl) mercapturic acid [40–44]. The principal mechanism associated with carcinogenicity and mutagenicity is conjugation of ethylene dibromide catalyzed by glutathione-S transferases [44, 45]. The conjugate rapidly rearranges to an episulfonium ion, which reacts with DNA [44, 46].

In a rat model, pretreatment with alcohol potentiated the hepatotoxicity of ethylene dibromide secondary to a reduction in ethylene dibromide conjugation, with a shift to the formation of reactive oxidative intermediates [47].

Ethylene Oxide

Ethylene oxide is one of the most common medical sterilants in use today. In addition to its use in the sterilization of medical devices, ethylene

oxide has found use as a fumigant, a fungicide, and an intermediate in the production of plastics. Although it often is discussed in terms of its mutagenic potential, it possesses the acute toxicologic properties of being a potent skin irritant and CNS depressant.

Ethylene oxide is a colorless gas at room temperature with an odor threshold of 250–690 ppm [48]. However, levels of 200 ppm may cause mucous membrane irritation. Direct skin contact with liquid ethylene oxide may cause significant cutaneous burns resembling toxic epidermal necrolysis [49]. Concentrations approaching 1000 ppm may cause chest pain, dyspnea, gastrointestinal disturbances, weakness, and ataxia [50]. Uncommon but life-threatening acute reactions include hemolysis and anaphylactoid reactions reported after exposure to ethylene oxide-treated cardiopulmonary bypass machines [51].

Acrylonitrile

Acrylonitrile (CH_2CHCN ; vinyl cyanide) is a colorless-to-pale yellow liquid with an unpleasant odor. It is highly flammable and when combusted or ingested may form cyanide gas. The vapor pressure of acrylonitrile is 100 mmHg (water is 25 mmHg), and its vapor density is 1.9 (air is 1). Acrylonitrile easily volatilizes but remains low to the ground unless disturbed by air currents. In addition to its use in the plastics industry, it may be used as a fumigant. Exposure to acrylonitrile may occur by the dermal, inhalational, or oral routes. In human volunteers inhaling 2.3 or 4.6 ppm of acrylonitrile, 52% of the administered dose was retained [52]. It is absorbed through the forearm skin at a rate of $0.6 \text{ mg/cm}^2/\text{h}$ [53].

Acrylonitrile is metabolized less efficiently in humans than in rodents, which may explain partially why the cyanide-like toxicity plays a lesser role in humans than in rodents [54]. Its proposed metabolic pathways are shown in Fig. 1. The typical half-life of acrylonitrile is approximately 3–6 h in rodents [55]. Four main metabolic products have been detected: glucuronides; glutathione adducts, which form cyanoethyl

Fig. 1 Proposed metabolic pathways of acrylonitrile metabolism. Note specifically the glutathione and rhodanese pathways

mercapturic acid; protein thiol group adducts; and 2-cyanoethylene oxide, which is formed by epoxidation. The latter two pathways are considered to be responsible for acrylonitrile's toxicity [38]. The toxic mechanism of nitriles is via the liberation of cyanide in vivo and in vitro [56].

Acrylonitrile may cause mucous membrane irritation, chest discomfort, dyspnea, and nausea at low doses. More significant exposure may cause loss of consciousness, seizures, respiratory arrest, and cardiovascular collapse if the dose is sufficient [57]. The acute systemic toxicity resembles cyanide poisoning, with the formation of lactic acidosis and cyanide [58, 59]. Liver and kidney injury may follow large exposures

[60]. When acrylonitrile is ingested, the signs and symptoms may be slower in onset than after inhalation [61].

Carbon Disulfide

Carbon disulfide (CS₂) is a colorless but volatile liquid. With proper engineering controls in the workplace, exposures are rare. Its vapor pressure is approximately 300 mmHg (water is 25 mmHg). Carbon disulfide has been used principally in the manufacture of rayon, in the manufacture of cellophane, and in the semiconductor industry. It also found use as a fumigant when mixed with carbon

tetrachloride in a 20:80 ratio. Such a mixture has been used to fumigate boxcars of grain [62, 63]. The major target organs are the CNS, eyes, skin, cardiovascular system, liver, and reproductive organs.

Acute effects of carbon disulfide are rare and generally are due to inhalation or dermal contact. An early effect of sufficient concentrations is irritation of the mucous membranes. After major skin contact, full-thickness corrosive burns may occur with erythema and blistering. A wide variety of neurologic effects have been described including psychosis, hallucinations, suicidality, insomnia, labile mood, paranoia, excessive sexual behavior, ataxia, parkinsonism, delirium, blurred vision, seizures, and microangiopathy [64–66]. Ingestion of carbon disulfide has been rarely reported, albeit with catastrophic features, including muscle spasms, Cheyne-Stokes respirations, hypotension, coma, and death [67].

Chlorine Dioxide

Chlorine dioxide (ClO_2) is a fumigant that also has found use in the bleaching of cellulose, flour, leather, and textiles. It is a yellow-to-red gas at room temperature, with an acrid odor; it is heavier than air; and it has a high vapor pressure (760 mmHg). This compound typically is not used in routine fumigation processes. In 2001, anthrax spores were disseminated via the US Postal Service. One site where anthrax spores were found was the Hart Senate Office Building in Washington, D.C. In this case, chlorine dioxide was pumped into the sealed building to soften and kill the spores. Because of chlorine dioxide's strong oxidizing properties, it was thought that it would be the most effective fumigant based on the size of the job and risk to the building's inhabitants and adjacent urban population. After the fumigation process, the air was filtered through a scrubber containing the antioxidant ascorbic acid, which reacts with chlorine dioxide to inactivate the biocide.

Chlorine dioxide is an irritant gas that affects the mucous membranes and other moist tissue

owing to its relatively high water solubility [68]. Expected clinical features are irritation of the eyes, nose, and throat [69]. Larger exposures may affect the tracheobronchial tree with the possibility of pulmonary irritation from very large exposures. Ingestion of this oxidizing agent would be expected to cause a corrosive injury to the gastrointestinal tract if the dose is sufficient. Chlorine dioxide is absorbed rapidly after ingestion or inhalation, with peak concentration occurring within 1 h [70]. Acute renal failure with acute tubular necrosis has rarely been reported [71].

One novel source of exposure includes people who use the Miracle Mineral Supplement for medicinal purposes. The sodium chlorite solution, when mixed with citric acid, produces chlorine dioxide, which has led to nausea, vomiting, diarrhea, and severe dehydration and a warning from the US Food and Drug Administration [72].

Treatment

In all cases of fumigant exposure, it is important to remove the patient from further exposure. Rescuers must wear proper personal protective equipment. In many instances, removing the patient from the source is all that is necessary if these fumigants are in their gaseous states. For significant exposures with signs and symptoms that do not resolve, prompt evaluation at a medical facility is indicated.

During decontamination procedures, care should be taken to prevent secondary contamination of rescue workers; this is especially true for methyl bromide and sulfuryl fluoride in their liquid states. Secondary contamination may occur because a victim's skin temperature usually exceeds the boiling points of these substances, which may result in their volatilization.

Decontamination procedures should begin with the physical separation of the offending agent and the victim. If the product was in a liquid or solid state and skin contact has occurred, it is necessary to remove all clothing and personal items from the patient because these may contain residual fumigant. Current recommendations for

duration of decontamination range from 3 to 30 min and rely on expert opinion, limited retrospective case series, and radiotagged chemical simulations that may not reflect real life scenarios [73]. As longer decontamination has been shown to decrease residual contamination, and there appears to be little downside, the authors recommend that exposed individuals should be decontaminated with mild soap and water for at least 15 min (Level of Evidence [LoE] III) [74]. A mild liquid detergent is necessary because these substances have low water solubilities (Table 2) (LoE III). Attention to exposed skin in skinfolds, the axillae, the genital area, feet, and hair is important. It is not recommended to wash clothing because further exposure may occur during the intervals before washing the clothing.

Specific ocular decontamination may not be needed for patients exposed to these fumigants in their gaseous states; however, if there is irritation or if significant chloropicrin exposure has occurred, it can be presumed that eye decontamination by irrigation would be beneficial, large quantities of water or sterile saline solution are probably best. Use of irrigation lenses with ophthalmic local anesthetics, such as proparacaine, may make decontaminating the eyes more comfortable.

The fumigants discussed in this chapter all have poor water solubility that would diminish the efficacy of hemodialysis (see Table 2), with the possible exception of methyl bromide.

Criteria for Discharge

1. Asymptomatic patients with incidental exposure may be discharged after an observation period of 6–8 h.
2. Patients with ingestions, prolonged exposure in confined spaces, or significant symptoms should be monitored until asymptomatic with stable vital signs.

Indications for Admission

Patients with significant fumigant exposures should be placed on a cardiac monitor and

observed for dysrhythmias. If dysrhythmias occur, American Heart Association advanced cardiac life support guidelines generally are sufficient, with the exception of the use of calcium as a specific antidote in sulfuryl fluoride poisoning. Specific details of the treatment of fluoride poisoning may be found in ► Chap. 102, “Hydrofluoric Acid.”

The patient’s level of consciousness should be assessed continually. If seizures develop despite adequate supportive care and blood glucose, the patient should be treated with intravenous diazepam or lorazepam (LoE III). Status epilepticus can occur, necessitating high doses of intravenous diazepam or lorazepam and possibly the addition of a barbiturate. Further guidance can be found in ► Chap. 20, “Toxicant-Induced Seizures.” Tetany or seizures due to sulfuryl fluoride poisoning should be treated with intravenous calcium in addition to intravenous diazepam or lorazepam. Monitoring of liver and renal laboratory markers on a daily basis is indicated if there have been major exposures to these agents.

Phosphides

Lavage with activated charcoal and potassium permanganate (1:10,000) has been described. Potassium permanganate has been theorized to oxidize phosphine to nontoxic phosphate. However, there are no clinical data supporting this intervention, and there is doubt about this mechanism [75–77]. Additionally, there are no data demonstrating benefit of activated charcoal in phosphide poisoning [78]. Animal studies and case reports suggest that oral administration of sweet almond oil can improve survival (LoE II-3) [79, 80]. Oral bicarbonate is also commonly co-administered to reduce conversion of phosphide to phosgene (LoE III). Other small trials have described improved survival in animals and humans given N-acetylcysteine (LoE III) [81–83].

Shock, altered mental status, hyperglycemia, and electrocardiographic changes have been associated with poor outcomes [84, 85].

Further details regarding the treatment of phosphide poisoning can be found in ► Chap. 94, “Phosphate and Phosphine.”

Ethylene Dibromide

There are no specific antidotes for ethylene dibromide poisoning, and supportive care is the mainstay of treatment. As ethylene dibromide is highly protein bound, it is not readily removed by hemodialysis. In patients with significant exposure, early serial plasma exchange (less than 24 h post exposure) has been associated with improved survival in comparison to those who received plasma exchange later (greater than 24 h after exposure) (LoE III) [86]. As the study was retrospective and lacked controls, it is unclear if improved survival reflects the importance of early intensive supportive care or early serial plasma exchange. Tachycardia is considered a poor prognostic indicator [87].

Although not studied, *N*-acetylcysteine is a theoretically beneficial sulfhydryl donor in these patients. *N*-Acetylcysteine is discussed in detail in the chapter devoted to this topic.

Methyl Bromide

Hemodialysis and peritoneal dialysis have been shown to rapidly decrease serum bromide levels [88, 89]. However, clinical effects and prognosis do not correlate with serum bromide levels following methyl bromide exposure (not to be confused with bromine exposure) [90]. As such, hemodialysis is not routinely advised in the absence of other indications such as renal failure or refractory acidosis (LoE III).

Methyl bromide is known to form methylcysteine adducts in albumin and globulin [91]. Though some authors have postulated benefits from *N*-acetylcysteine, dimercaprol, or BAL there have been no convincing studies in human exposures to support their use (LeE III) [16, 92].

Acrylonitrile

Acrylonitrile is oxidized by the mixed-function oxidase pathway to an oxide (see Fig. 1). This oxide is metabolized further by epoxide hydrase, which releases cyanide. Most cases involve minor exposure, however, which resolve with supportive care. Human and animal data suggest that toxicity from acrylonitrile exposure may be mediated via the cyanide metabolite [93]. *N*-acetylcysteine may shift metabolism of acrylonitrile towards less toxic glutathione conjugation products and away from the oxidative pathway responsible for cyanide generation [60]. Given the safety profile of *N*-acetylcysteine and its history of use for acrylonitrile poisoning in Europe, patients with mild symptoms should receive *N*-acetylcysteine 150 mg/kg intravenously over 1 h (LoE III) [94]. Animal studies have supported use of sodium thiosulfate for treating severe acrylonitrile toxicity, similar to its use in cyanide exposure [95]. Another cyanide antidote, hydroxocobalamin, may also be beneficial in treating severe acrylonitrile toxicity. In patients exposed to acrylonitrile who are demonstrating signs of cyanide toxicity, altered mental status or lactate-associated metabolic acidosis, providers should administer hydroxocobalamin or sodium thiosulfate (LoE III). Animal models suggest the combination of cyanide antidote with sulfur-containing amino acids (similar to *N*-acetylcysteine) has a pronounced prophylactic effect when looking at mortality as an end point [95].

Fungicides are a diverse group of structurally unrelated compounds that are widely used for agricultural, industrial, and domestic purposes. As a group, fungicides are responsible for a small proportion of human toxic exposures leading to acute morbidity and mortality. In 2013, regional poison control centers across the United States reported 1,054 cases of fungicide-related toxicities. Of these, only three cases reported life-threatening or disabling outcomes, and no deaths were reported [1]. Despite these findings, fungicides are important from a historical as well as an international health perspective. Some of the most serious poisoning epidemics of the twentieth century have been attributed to accidental fungicide exposures. Lessons learned from these disasters have led to severe restrictions or the discontinuation of several classes of fungicides, such as methylmercury and hexachlorobenzene (HCB). Unfortunately even with these restrictions, the acute and chronic effects of some exposures continue to pose diagnostic and therapeutic challenges.

This chapter is divided into six subsections based on chemical classifications of fungicides clinically relevant to the critical care physician (Table 1). Several of the modern organic fungicides (Table 2) are not discussed in detail. In general, many of the modern organic fungicides have irritant effects on the skin and mucous membranes, although systemic effects and acute poisonings have not been widely reported. When presented with a case of suspected fungicide poisoning, it is important for the clinician to recognize that other ingredients in the pesticide formulation, including solvents or adjuvants, may be important contributors to overall toxicity. When the other ingredients of the pesticide formulation are uncertain, the manufacturer may be able to provide additional specific information useful in identifying additional hazards.

The manufacturer of benomyl (Benlate) voluntarily canceled sales and production of this widely used fungicide, citing difficulties encountered in defending the product from claims of adverse human health effects and environmental impact. Although benomyl has been suggested to be a weak dermal sensitizer [2], reports of reproductive

Table 1 Major classifications of clinically relevant fungicides

Organomercury compounds (methylmercury, phenylmercuric acetate)
Chlorinated phenols (pentachlorophenol)
Substituted benzenes (hexachlorobenzene)
Dithiocarbamates (metam sodium, thiram, ethylene bisdithiocarbamate compounds)
Copper compounds (copper sulfate)
Organotin compounds (triphenyltin, tributyltin oxide)

Table 2 Miscellaneous organic fungicides (trade names)

Benomyl (Benex, Benlate, Tersan 1991)
Captan (Orthocide, Captan, Merpan)

Dodine (Carpene, Curitan, Melprex, Venturol)
Etridiazole (Aaterra, Ethazol, Koban, Pansoil, Terrazole, Truban)
Iprodione (Glycophene, Rovral)
Metalaxyl (Ridomil, Subdue)
Strobilurin (Abound, Bas, Cabrio, Headline, Honor)
Thiabendazole (Apl-Luster, Arbotect, Meretect, Tecto, Thibendazole)
Triadimefon (Amiral, Bayleton)
Triforine (Denarin, Funginex, SaproI)

toxicity (anophthalmia and microphthalmia) do not seem to be supported by the weight of the scientific evidence [3, 4].

Organomercury Compounds

Organomercury compounds are a class of fungicides formulated as dusts and aqueous solutions that are used primarily as seed protectants. Although their use has been banned or greatly restricted in many countries, they are of historical importance because of their severe toxicity in humans. In 1971, a poisoning epidemic in rural Iraq was the result of the people ingesting bread prepared from wheat treated with methylmercury – acting as a fungicide. This outbreak resulted in 50,000 exposures and at least 439 deaths [5]. The scientific study of this tragedy has provided further insight into the toxic effects of methylmercury on the central nervous system (CNS).

Biochemistry and Pharmacokinetics

Organomercury fungicides (Fig. 1) can be divided into short-chain alkyl (e.g., methylmercury) and aryl (e.g., phenylmercuric acetate) compounds. Their absorption, distribution, and metabolic fate are dependent upon their chemical structure [6]. Ingestion is the predominant route of human exposure to methylmercury, since absorption is nearly complete across the gastrointestinal tract. Methylmercury has a high volume of distribution and is readily transferred across the blood–brain and placental barriers. When absorbed, more than 90% of methylmercury detected in blood is bound to hemoglobin. About 10% of the body burden of methylmercury is found in the brain, where it undergoes a slow metabolic transformation into inorganic mercury, becoming relatively fixed in neural tissue [6]. CNS injury is likely due to neuronal apoptosis at low concentrations and necrosis at higher concentrations [7]. It is unclear whether the CNS injury is likely due to methylmercury, inorganic mercury, or the biotransformation process between the two forms. Human's major route of excretion is biliary and fecal elimination, with a whole-body half-life of approximately 70–80 days [6]. Approximately 10% of a given dose of methylmercury is excreted in urine [6].

Pharmacokinetics of Methylmercury

Volume of distribution: >1 L/kg

Protein binding: >90%

Mechanisms of clearance: 90% biliary, 10% renal

Active metabolite: inorganic mercury

Methods to enhance clearance: DMPS (?), DMSA (?)

In contrast to short-chain alkyl compounds, phenylmercuric acetate is not well absorbed through the gastrointestinal tract and undergoes more rapid transformation into inorganic mercury [6]. Dermal absorption and inhalation may be important routes of exposure to phenylmercuric acetate. A case of acrodynia was reported in a child whose house was painted with latex paint

Methylmercury

Phenylmercuric acetate

Fig. 1 Chemical structures of organomercurials.

containing phenylmercuric acetate [8]. In a follow-up epidemiologic study, higher levels of mercury were found in the urine of individuals whose houses had been recently painted with products containing phenylmercuric acetate as a preservative [8].

Pathophysiology

The pathophysiology of inorganic mercury toxicity is believed to relate to its ability to form covalent bonds with protein's sulfhydryl groups, resulting in enzyme dysfunction and cellular toxicity [9]. The biochemical mechanism of toxicity from methylmercury exposure is complex and not well understood [10]. It has been theorized that the damage may be due to dysregulated release of neurotransmitters at the presynaptic terminals mediated by changes in intracellular calcium concentrations. Chronic exposures lead to mitochondrial structural changes with accumulation of methylmercury within the mitochondria, where it may lead to inhibition of mitochondrial enzymes causing inhibited protein synthesis, induction of lipid peroxidation, mitochondrial changes, and microtubule dysfunction [11]. However, no single mechanistic pathway has yet been identified.

Clinical Presentation

The clinical course of methylmercury poisoning is most remarkable for its effects on the CNS

[12]. The cardiovascular, renal, and gastrointestinal systems are not usually significantly affected [13]. A latent period of 2–8 weeks between the time of exposure and the onset of symptoms has been described. Initial signs and symptoms include peripheral and perioral paresthesias, followed by prominent cerebellar findings, including incoordination, ataxic gait, and dysarthria [13]. Visual disturbances are frequently present, consisting of constriction of the visual field, reduced acuity, abnormal funduscopic examination, and blindness [12]. Audiologic impairment and dysequilibrium are also frequently reported [12]. Emotional lability, confusion, and delirium develop in severe cases. Most fatalities are attributed to respiratory failure [13].

Diagnosis

Mercury can be measured in whole blood and urine using atomic absorption spectroscopy. Blood is generally considered the most appropriate biomarker of acute methylmercury exposure [14]. There are conflicting data on the correlation between blood mercury levels and clinical findings after methylmercury poisoning, an observation that might be attributed to differences in the timing of clinical presentation and specimen collection [12, 15]. If blood mercury measurements are obtained after distribution to the CNS and other tissues is complete, the blood level may underestimate the total-body mercury burden. Although methylmercury distributes and accumulates in the kidneys, a relatively small proportion of methylmercury undergoes renal excretion (10%), as such urine mercury concentrations are less useful than concentrations in blood in the diagnosis of methylmercury poisoning [6]. Urine mercury concentrations are useful, however, in monitoring response to chelation therapy. Compared with whole-blood mercury measurements, urine mercury concentrations are a more valid biomarker of exposure to phenylmercuric acetate, which is rapidly converted to inorganic mercury after absorption [8].

Methylmercury incorporated into hair is stable, and hair analysis using various analytical techniques has been used to document the timing of

exposure in epidemiologic studies [16, 17]. Hair analysis may be useful in the diagnosis of methylmercury exposure occurring in the weeks or months before presentation. An important source of error in hair analysis for mercury is the presence of inorganic mercury from environmental contamination, an error that may be reduced by washing the sample before analysis [18]. When considering sending mercury levels, careful history should be obtained since cosmetic applications of mercury-containing products may result in elevated levels. All of the methods used to measure mercury in biologic specimens are subject to considerable variation as a result of contamination during preparation and analysis. Only an experienced laboratory should perform the collection and analysis of specimens.

Treatment

The clinical management of organomercury intoxication begins with the identification and removal of the source of exposure. For the majority of methylmercury ingestion cases, the development of symptoms occurs after a considerable latent period, which limits the potential benefit, if any, of gastrointestinal decontamination [12, 13]. Owing to the extensive enterohepatic recirculation of methylmercury [6], orally administered thiolated resin has been investigated as a means to enhance elimination. In one study [15], thiolated resin was found to significantly decrease the blood half-life of methylmercury-exposed adults and children, although there was no observed improvement in clinical signs and symptoms. In one of the cases treated with thiolated resin, an individual with an initial blood mercury concentration of 3,622 ppb and mild neurologic signs at presentation had no further deterioration in neurologic status on longitudinal follow-up. In the same study, other treatment groups received sodium 2,3-dimercaptopropane-1-sulfonate (DMPS), penicillamine, and *N*-acetyl-D,L-penicillamine (an experimental analogue of penicillamine). Treatment with each of these agents resulted in a significant decrease in the blood half-life compared with untreated controls. DMPS was reported to have the best efficacy

(Grade II-3 evidence). Although no adverse effects were noted, none of these therapies resulted in observable clinical improvement. This finding is consistent with more recent reports of poisoning with organomercury compounds, in which the therapeutic benefit of chelating agents has been questionable [19].

Indications for ICU Admission in Methylmercury Poisoning

Cerebellar signs
Visual impairment
Delirium

Although dimercaprol (British anti-Lewisite; BAL) is considered the chelator of choice in the treatment of acute inorganic mercury poisoning. Based on experimental animal data suggesting that organomercurials may be redistributed to the brain after the administration of dimercaprol [20], it is not recommended as a therapeutic option in the treatment of methylmercury or phenylmercury toxicity. The role of dimercaptosuccinic acid (DMSA) has not been defined in methylmercury toxicity. In a case report of dimethylmercury poisoning, DMSA has been used effectively to enhance the urinary elimination of mercury; however, no clinical improvement was observed [19]. A larger trial involving workers after an industrial exposure to elemental mercury found that when some of the exposed workers were given DMSA, they had a fivefold rate of urinary mercury excretion [21]. The limited available human data suggest that the initiation of chelation therapy after serious neurotoxicity has developed provides little to no clinical benefit [16]. In the absence of data supporting the safety and clinical efficacy of chelating agents, a grade III recommendation against the routine use in methylmercury poisoning is made. The large volume of distribution and extensive protein binding of methylmercury predicts that extracorporeal removal techniques would not be successful in enhancing the elimination of the compound, thus it is not recommended as a removal technique. This recommendation is based on expert opinion and receives a grade III recommendation.

Criterion for ICU Discharge in Methylmercury Poisoning

Resolution of neurologic symptoms

Special Populations

Studies of intrauterine exposure to methylmercury have identified gross impairment of motor and mental development among infants whose mothers were exposed to high levels of methylmercury during pregnancy [22, 23]. A follow-up of methylmercury-exposed Iraqi infants over 2 years found that most children showed considerable neurologic improvement; an exception to this, however, was infants that were most severely affected at birth [24].

Common Misconceptions About Methylmercury Poisoning

1. Chelation may improve clinical outcomes.
2. Toxicokinetics is similar to that with inorganic mercury.

Key Points in Methylmercury Poisoning

1. Predominant effects are neurologic (central nervous system).
2. Symptoms may develop after considerable latency.
3. No specific antidote is available.

Pentachlorophenol

Due to its broad antimicrobial properties, pentachlorophenol (PCP) (Fig. 2) and its sodium salt have been used extensively as a biocide and wood preservative in industry for many years. Although its availability to the general public has been restricted in the United States and other countries, PCP continues to have wide industrial application as a fungicide and wood preservative. There have been several historical accounts of acute poisoning caused by PCP exposures. In 1967, a cluster of cases of critical illness in a newborn nursery occurred as a result of the misuse of sodium

Fig. 2 Chemical structure of pentachlorophenol

pentachlorophenate as an anti-mildew agent in the hospital laundry; nine poisoning cases and two fatalities were reported [25]. This and other accounts of accidental occupational exposures provide ample toxicologic evidence of the risks from acute exposure to PCP [26, 27].

Biochemistry and Pharmacokinetics

PCP exists as colorless crystals that produce a sharp, phenolic odor when heated. While PCP is largely insoluble in water (14 mg/L), the sodium salt of PCP can be dissolved in water (330,000 mg/L). PCP has considerable environmental persistence, with a reported half-life of 5 years in soil [27]. The industrial production of PCP can yield unwanted contaminants, including dioxins. Although the detection of dioxins may be of concern for the development of chloracne, its presence as a contaminant in commercially available solutions of PCP is debated, and suppliers in some countries, including the United States and Canada, are now required to limit the content of certain dioxins (Hexachlorodibenzo-para-dioxin and 2,3,7,8-tetrachlorodibenzo-para-dioxin) in their products [28].

Pharmacokinetics of Pentachlorophenol

Volume of distribution: >1 L/kg

Protein binding: >90%

Mechanism of clearance: renal

Active metabolites: none

Methods to enhance clearance: exchange transfusion in neonates (?)

Human exposure to PCP can occur through dermal absorption, ingestion, or inhalation of vapors. Percutaneous absorption is an important route of exposure in neonates and adults. Accidental poisoning has been described in the occupational setting after dipping wood in liquid PCP formulations, immersing unprotected hands in solution, and applying PCP to wood products [27]. The epidemic of critical illness described among newborns suggests that even dermal contact with articles inappropriately treated with PCP (diapers, linens, blankets) may result in significant toxicity.

Pathophysiology

The pathophysiology observed in PCP toxicity develops as a result of the uncoupling of oxidative phosphorylation [29]. As a lipophilic weak acid, PCP can migrate across the inner mitochondrial membrane, bypassing the normal flow of protons of the electron transport chain that lead to the production of adenosine triphosphate (ATP). In this way, the normal process of capturing energy in the formation of ATP is altered. Since the energy generated cannot be stored as ATP, it is instead released as heat. This effect is most pronounced in organ systems dependent on high-perfusion and oxygen delivery, including the kidneys, heart, and CNS. On pathologic evaluation vacuolization of hepatocytes, proximal tubular cells, and myocardial tissue, as well as signs of mitochondrial injury have been shown in fatal cases involving neonates and adults [26, 30]. Pentachlorophenol is also an inducer of cytochrome CYP3A [31], which could influence the metabolism of other drugs used in the critical care management of poisoned patients (e.g., diazepam, alprazolam, and midazolam).

Clinical Presentation

The clinical features attributed to PCP toxicity are best explained by the uncoupling of oxidative phosphorylation. Fever, tachypnea, tachycardia, and marked diaphoresis, all signs of a hypermetabolic state, are the most consistent

findings [25–27]. Additional physical examination findings include hepatosplenomegaly in affected neonates [25]. Early in the clinical course, mental status is usually normal, despite the presence of moderate fever, although progression to confusion, delirium, and coma occurs rapidly [25–27]. In one adult case of occupational exposure to PCP, the patient developed a core temperature of 105 °F, and death occurred within 1 h of presentation, despite aggressive cooling measures [26].

Diagnosis

Laboratory findings in PCP poisoning reflect the uncoupling of oxidative phosphorylation. A high anion gap metabolic acidosis is commonly observed, particularly in neonates [25]. Ketonemia and ketonuria are also common findings [30]. In severe cases, rhabdomyolysis has been reported, with resultant elevation in serum creatine phosphokinase and myoglobinuria [27]. Less specific laboratory findings include elevation in the blood leukocyte count and proteinuria [27]. A consistent finding at autopsy is the almost instantaneous onset of extreme rigor mortis. This has been described as a hallmark of PCP poisoning [26, 27, 32]. PCP can be detected in serum, urine, and other body fluids by gas chromatography, although measurements obtained from cases of intentional or accidental poisoning can be comparable to levels found in unexposed controls, limiting their prognostic value [26].

Treatment

The clinical management of PCP toxicity requires the identification of, and removal from, the source of exposure. The skin can be decontaminated thoroughly with soap and water if dermal exposure is suspected. Based on its physical properties, the adsorption of PCP to activated charcoal is predicted to be poor, thus limiting its therapeutic benefit in single or repeated doses, leading to a grade III recommendation against its empiric administration.

Successful management of PCP toxicity relies on the early recognition and aggressive

management of hyperthermia and its complications. Continuous monitoring of core body temperature is necessary to monitor the response to therapy. Passive cooling techniques (administration of intravenous fluids, cooling blankets, ice bath immersion) should be instituted immediately and are given as grade III recommendation. Consideration of iced gastric lavage may be of therapeutic benefit in the setting of hyperthermia and may also lead to decontamination. Given the pathophysiology of PCP toxicity, antipyretics would not be expected to be of any therapeutic benefit. Salicylates are theoretically contraindicated due to the potential to worsen the hyperthermia through further uncoupling of oxidative phosphorylation.

No effective antidote for PCP poisoning has been identified. The mainstay of therapy is aggressive supportive management in a critical care unit. Invasive hemodynamic monitoring may be used for standard indications. Exchange transfusion has been used successfully in the management of neonates with PCP toxicity [30]. In all patients treated with exchange transfusion, dramatic clinical improvement was described immediately after the procedure. One of the patients with less severe clinical signs did not undergo exchange transfusion and recovered uneventfully. In this case series, it is unclear whether the successful outcomes could be attributed to exchange transfusion or earlier recognition of the diagnosis. A grade II-3 recommendation is made for the use of exchange transfusions as a therapy in infants to enhance the elimination of PCP.

PCP is a highly lipophilic compound. Lipid emulsion has been used in the management of toxicity due to lipophilic compounds such as local anesthetics. No data is available on the use of lipid emulsion in PCP; however, it has an octanol coefficient of 3.3 at a pH of 7.25 (measure of lipophilicity) similar to that of amitriptyline (octanol coefficient of 3.0 at pH of 7.4) for which there have been limited reports of success in overdoses after intervention with lipid emulsion. Thus, in a severe toxicity scenario, use of lipid emulsion may be worth pursuing and is given a grade III recommendation [33, 34]. There are no data indicating that this treatment changes the outcome in PCP poisoned patients.

**Indications for ICU Admission
in Pentachlorophenol Poisoning**

Fever
Tachycardia
Metabolic acidosis

**Criteria for ICU Discharge in Pentachlorophenol
Poisoning**

Hemodynamic stability
Absence of hyperthermia

Although some authors have recommended forced diuresis as a means to enhance PCP elimination [35], the data supporting this approach are based on computer-simulated pharmacokinetic models, whereas the toxicokinetics of PCP remains poorly understood. There is no controlled evidence that forced diuresis improves clinical outcomes, and for this reason the emphasis on fluid management in PCP toxicity should focus on restoring and maintaining normal hemodynamic function.

**Common Misconception About
Pentachlorophenol Poisoning**

Forced diuresis improves outcomes in pentachlorophenol toxicity.

Key Points in Pentachlorophenol Poisoning

1. Hyperthermia and diaphoresis are common clinical findings.
2. Severe toxicity may develop following exposure.

Hexachlorobenzene

Of the substituted benzene fungicides, hexachlorobenzene (HCB) (Fig. 3) is the best studied. Although the acute toxicity from ingestion or inhalation exposure is low with HCB, the systemic effects from chronic exposure are well documented. Between 1955 and 1959, an epidemic of 5000 cases of porphyria cutanea tarda (PCT) was described in

Fig. 3 Chemical structure of hexachlorobenzene

Turkey [36]. The cause was traced to the consumption of wheat treated with a seed protectant containing 10% HCB. HCB has been detected frequently as a contaminant in the industrial production of many chlorinated solvents, which may be important in the context of occupational and environmental exposures. Although single case reports have reported PCT in association with occupational exposure to HCB, larger-scale epidemiologic studies have not confirmed this relationship [37]. The differences in clinical manifestations between occupational exposure to HCB and the outbreak in Turkey may be related to the dose, duration, and route of exposure. Other substituted benzene formulations continue to be used as fungicides in the United States, although systemic poisonings and PCT have not been widely reported with these compounds.

Biochemistry and Pharmacokinetics

HCB (see Fig. 3) is a chlorinated aromatic hydrocarbon that is highly lipid soluble and well absorbed from the gastrointestinal tract [38].

Pharmacokinetics of Hexachlorobenzene

Volume of distribution: >1 L/kg

Protein binding: 45%

Mechanism of clearance: >90% fecal

Active metabolite: pentachlorophenol (clinically insignificant)

Methods to enhance elimination: none

Pathophysiology

Animal studies have shown that when absorbed, HCB has a large volume of distribution and bioaccumulates in adipose tissue [38]. Altered heme synthesis is induced by HCB through the inhibition of uroporphyrinogen decarboxylase activity, leading to the accumulation of uroporphyrin and the induction of aminolevulinic acid synthetase. Consistent with other organochlorine compounds, HCB is capable of inducing several families of the cytochrome P-450 system. Toxicokinetic data in humans are not readily available, but an investigation of a population with a high level of HCB due to high airborne exposures associated with a chlorinated solvent factory suggested that excretion occurs predominantly through the feces [39]. A small proportion appears in the urine as chlorinated phenols, including PCP, although signs of toxicity relating to this metabolite have not been reported in individuals with high body burdens of HCB.

Clinical Presentation

The latency between exposure and the development of signs and symptoms of PCT varies depending on dose, but epidemiologic studies suggest a delay of several months after repeated ingestion [40]. In mild cases, early skin lesions consist of bullae containing clear fluid, occurring in sun-exposed areas (particularly the face and hands). The skin is unusually sensitive, and the epidermis easily rubs off from slight mechanical trauma (Nikolski’s sign) [40]. The bullous lesions may subsequently burst and become infected, forming pigmented scars and contractures. In addition, there is marked hypertrichosis throughout the body. Weight loss and hepatomegaly are frequently present, usually without abdominal pain or neurologic symptoms [41]. These clinical findings distinguish PCT from acute intermittent porphyria, another disease associated with abnormal heme biosynthesis in which abdominal pain and neuropsychiatric symptoms are frequently prominent.

Table 3 Laboratory diagnostic patterns of porphyria cutanea tarda

Urine concentration
Porphobilinogen and aminolevulinic acid are not increased
Uroporphyrinogen is increased greater than heptacarboxylate
Fecal porphyrins
Isocoproporphyrinogen, heptacarboxylate present
Erythrocyte porphyrins
Not increased

Diagnosis

In addition to the prominent dermatologic signs of toxicity, the diagnosis of PCT can be supported on the basis of urinary findings. A dark red urine, which under Wood’s light exhibits intense red fluorescence, has been described [41]. In contrast to other types of porphyria, urine concentrations of porphobilinogen and aminolevulinic acid are not increased, although elevated levels of uroporphyrinogen may be detected [42]. Table 3 summarizes urinary, fecal, and erythrocyte porphyrin findings suggesting PCT. Evidence of mild iron overload (elevated ferritin) frequently is present [42]. HCB may be measured in blood using gas chromatography, although a reference range is not established, and a threshold dose that corresponds with the development of PCT is not known [37, 39].

Treatment

No specific antidote for HCB-induced PCT has been identified, and no specific methods of gastric or skin decontamination have been reported. A case series has described the use of oral and intravenously administered ethylenediaminetetraacetic acid (EDTA) in the clinical management of PCT associated with HCB ingestion [43]. The administration of EDTA was reported to transiently increase the excretion of porphyrin, which was associated with improvement in skin lesions and weight gain. Given the single nature of this study, a grade III recommendation is

given. Studies in rats have shown that HCB is eliminated fecally via nonbiliary transfer within the large intestine. In these experiments, oral treatment with mineral or hexadecane resulted in enhancement of elimination. Current grade III therapeutic recommendations for PCT include avoidance of sunlight exposure and supportive management, with special attention to skin care [42]. Phlebotomy may be effective therapy in PCT to deplete excess iron stores, and the avoidance of alcohol and exogenous estrogens has been recommended and is given a grade III recommendation [42]. Low-dose hydroxychloroquine (Plaquenil) has been investigated as a therapeutic agent for PCT in controlled studies and has been reported to be safe and effective at normalizing urinary porphyrin excretion and improving skin lesions. Thus, it is given a grade II-1 recommendation [44].

Indications for ICU Admission in Hexachlorobenzene Poisoning

Extensive skin involvement (>10% body surface area)

Superinfection of skin lesions

Criterion for ICU Discharge in Hexachlorobenzene Poisoning

Resolution of skin lesions and infection

Special Populations

In the epidemic of PCT in Turkey, a second disorder called *pembe yara*, or *pink sore*, was described in breast-fed infants of mothers who had PCT or had ingested HCB-contaminated bread [42]. Symptoms and signs included pink cutaneous lesions, fever, diarrhea, vomiting, weakness, hepatomegaly, and convulsions. The skin lesions characteristic of PCT were not observed in these infants, and the mortality rate was high (95%). No porphyrinuria was observed in these infants.

Common Misconceptions About Hexachlorobenzene Poisoning

1. Chelation is effective therapy.
2. Porphyrin cutanea tarda and acute intermittent porphyria are the same disease.
3. Infants exposed via breastmilk will experience similar symptoms to adults.

Key Points in Hexachlorobenzene Poisoning

1. Skin manifestations include bullous lesions and generalized hypertrichosis.
2. Breakdown of bullous lesions can lead to scarring and contractions.
3. Urinary findings may provide important diagnostic clues.

Dithiocarbamates

As a class of general- and restricted-use fungicides, the dithiocarbamates are available in a variety of formulations, including water suspensions, wettable powders, and dusts. They have many agricultural applications, including the protection of seedlings, turf, vegetables, fruits, and ornamentals from fungal growth. Compared with the known toxicity of several of the classes of fungicides described above, the dithiocarbamates have considerably lower acute toxicity due to their rapid metabolism and lack of persistence in mammalian systems. In contrast to the *N*-methyl carbamates, dithiocarbamates have poor efficacy as insecticides because they do not have significant effects on cholinesterase activity [45]. Certain dithiocarbamates warrant further discussion, due to their potential for causing acute illness through several different mechanisms.

Biochemistry and Pharmacokinetics

The chemical structure and environmental fate of the dithiocarbamates are predictive of their spectrum of toxicity (Fig. 4). Metam sodium is an aqueous solution used as a soil biocide and

Metam-sodium (dithiocarbamate)

Methyl isothiocyanate

Fig. 4 Chemical structure of dithiocarbamate and its decomposition product, methyl isothiocyanate

fumigant. Although it is nonvolatile, it quickly degrades on soil or water contact to produce methyl isothiocyanate, leading to its fungicidal activity. Thiram is another important dithiocarbamate due to being a known skin sensitizer and a common component of natural rubber latex. Other subclasses of the dithiocarbamate family, the metallobisdithiocarbamates and ethylene bisdithiocarbamates, are named for the metallic component in their formulation (zinc, manganese, iron). These subclasses do not interact with acetaldehyde dehydrogenase.

Pharmacokinetics of Dithiocarbamate

Active metabolites: carbon disulfide (all dithiocarbamates); methyl isothiocyanate (metam sodium)

Methods to enhance elimination: none

Pathophysiology

Metam sodium and thiram are thiurams, in the same chemical class as disulfiram (Antabuse), and theoretically could induce a disulfiram-like reaction in a susceptible individual through inhibition of acetaldehyde dehydrogenase. Methyl isothiocyanate is a potent mucosal irritant, and its effects have been observed well below the threshold for odor detection [46]. The toxicokinetic profiles of dithiocarbamates have not been studied in humans.

Clinical Presentation

Contact dermatitis and upper airway irritation are the most common clinical presentations following dithiocarbamate exposure. Workers involved in the cleanup of an accidental metam sodium spill into the Sacramento River developed erythema, rash, itching, and scaling of the lower extremities (the areas that had come into contact with contaminated water) [47, 48]. The same chemical spill resulted in the emergency triage of 360 individuals, most of whom had mild irritant upper airway symptoms that did not require hospitalization [49]. A follow-up study of adults living within 0.5 mile of the site of the accident identified 20 cases of persistent irritant-induced asthma and 10 cases of persistent asthma exacerbations [46]. Although effects consistent with aldehyde dehydrogenase inhibition were not reported in this cohort, a few case reports have described signs and symptoms consistent with a disulfiram-like reaction after individuals consumed ethanol following the use of topical products containing thiram [50]. A retrospective study of all calls received between 1992 and 2009 to the Poisons and Toxicovigilance Centre of Angers University Hospital serving the western region of France revealed 102 true exposures. The authors of this study revealed rapid recovery among 101 of those exposed and 1 death that was likely complicated by asphyxia. A review of symptoms included: eye irritant (76), nose and throat irritant [65], skin erythema [1], vomiting [3], nausea [7], cough [3], mild dyspnea [1], nausea [4], headaches [6], asthenia [3], dizziness [1], malaise [1], and paraesthesias [2]. In this case series no disulfiram reactions were observed despite two patients having consumed alcohol after exposure. However, these were the same individuals who reported a strange taste in their mouths.

Other systemic effects purportedly related to dithiocarbamate exposure have been described, although the results of these studies are not conclusive. A case report of severe CNS depression and hypothermia in a 7-year-old child has been reported in association with maneb. In this case, there was no clear history of exposure to the

fungicide, except for a laboratory detected level of maneb in a blood sample [51]. A single case of Henoch-Schönlein purpura was reported, and it was temporally associated with thiram exposure in a tree planter [52]. The exposure history consisted of falling down a hillside while carrying a bag of seedlings treated with a solution of 42% thiram. There have been no similar cases of acute renal failure or Henoch-Schönlein purpura reported in association with dithiocarbamate exposure. Signs and symptoms consistent with manganese toxicity, including muscle rigidity with cogwheeling, nervousness, and, memory problems, have been associated with chronic occupational exposure to maneb in a case-control study [53], although no significant difference in blood manganese concentration was noted between cases and controls.

Diagnosis

Dithiocarbamates undergo metabolism in mammals into ethyleneurea. Gas chromatography-mass spectrometry has been used to identify and quantify exposures in Italian vineyard workers for the presence of ethyleneurea while being monitored via urinary spot samples. Unfortunately, this testing does not occur quickly and requires specialized laboratory resources. As such, diagnosis depends on a careful exposure history and physical examination.

Treatment

When dermal exposure is suspected, decontamination with soap and water is indicated. When inhalational exposure to metam sodium or its breakdown product, methyl isothiocyanate, is suspected, respiratory distress or signs of obstruction can be treated with supplemental oxygen, inhaled bronchodilators, and continuous pulse oximetry monitoring in an intensive care unit. The treatment of isocyanate exposure is described further in the chapter on isocyanates. If a disulfiram-like reaction is apparent, standard supportive symptomatic management is indicated.

Indications for ICU Admission in Dithiocarbamate Poisoning

Respiratory distress

Severe disulfiram (Antabuse) reaction (tachycardia, hypotension, refractory vomiting)

Criteria for ICU Discharge in Dithiocarbamate Poisoning

Resolution of signs of respiratory distress

Hemodynamically stable

Common Misconception About Dithiocarbamate Poisoning

Dithiocarbamates affect cholinesterase activity.

Key Points in Dithiocarbamate Poisoning

1. Primary clinical effects are dermatologic (irritation, sensitization).
2. Decomposition product of metam sodium is a potent mucosal irritant.
3. Disulfiram (Antabuse) reaction is possible with certain dithiocarbamates.

Copper Compounds

Several copper compounds are available as fungicides for commercial use. Intentional and accidental ingestion of copper compounds has historically been a common cause of morbidity and mortality outside the United States, an observation that may be related to their widespread international availability and use [54].

Biochemistry and Pharmacokinetics

The soluble copper salts (e.g., copper sulfate) are not well absorbed across the skin or gastrointestinal tract. The organic copper compounds (copper

naphthenate, copper quinolinolate) have a higher bioavailability [55].

Pharmacokinetics of Copper Compounds

Volume of distribution: >1 L/kg

Protein binding: >90%

Mechanism of clearance: >90% biliary

Active metabolites: none

Methods to enhance clearance: dimercaprol (?), calcium ethylenediaminetetraacetic acid (?)

Pathophysiology

The predominant mechanism of toxicity of copper compounds is through mucous membrane irritation and corrosive effects on the gastrointestinal tract. Corrosive injury is discussed in detail in ► Chap. 101, “Caustics.”

Clinical Presentation

With massive ingestions, greenish blue emesis, hematemesis, and melena may develop [56]. Acute effects on the liver include jaundice and pathologic findings of centrilobular necrosis [57]. Intravascular hemolysis, Heinz body formation (precipitation of oxidatively denatured hemoglobin), and methemoglobinemia (► Chap. 30, “Toxicant-Induced Hematologic Syndromes”) have also been described [58].

Diagnosis

Copper concentrations may be measured in serum, whole blood, and urine using atomic absorption spectroscopy and inductively coupled plasma-atomic emission spectroscopy. There are also sensitive colorimetric assays for copper. In one case series, whole-blood copper concentrations greater than 2.87 mg/L (45.9 $\mu\text{mol/L}$) correlated with gastrointestinal symptoms, and levels greater than 7.98 mg/L (127.7 $\mu\text{mol/L}$) correlated with hepatorenal

dysfunction or shock [59]. In this case series, whole-blood copper levels correlated better than serum copper concentrations with the severity of clinical illness. Urine levels have been investigated in the diagnosis of diseases associated with copper excess (Wilson’s disease), although their diagnostic and prognostic value in copper fungicide exposures has not been evaluated.

Treatment

The role of gastrointestinal decontamination after accidental or intentional ingestion is simplified because spontaneous emesis is expected after significant ingestion of copper compounds. No data supports the efficacy of activated charcoal to decrease absorption of copper compounds after accidental or intentional ingestions.

Because of the corrosive gastrointestinal injury associated with acute copper exposure, parenteral chelators, such as dimercaprol and calcium disodium edetate, theoretically would be considered the therapy of choice after significant exposures. There are few pharmacokinetic studies to guide appropriate dosing of these agents [57], and their safety and efficacy for acute copper poisonings have not been established. In one case report of intentional copper and zinc sulfate ingestion, chelation therapy with dimercaprol and penicillamine was found to not be of clinical benefit [60]. The potential therapeutic benefit of other orally available chelating agents, such as DMSA, in acute copper toxicity has not been studied, thus would not be recommended at this time. The use of these chelators for other heavy metal poisonings is described in other chapters.

Indications for ICU Admission in Copper Compound Poisoning

Hematemesis

Shock

Signs of significant hepatic injury

Renal failure

Criteria for ICU Discharge in Copper Compound Poisoning

Resolution of gastrointestinal symptoms and signs

Hemodynamic stability

Common Misconception About Copper Compound Poisoning

Chelation therapy is safe and effective for copper fungicide exposures.

Key Points in Copper Compound Poisoning

1. Corrosive gastrointestinal effects develop after ingestion.
2. Hepatic injury and necrosis may develop.
3. Oxidative injury and methemoglobinemia have been described.

Tributyltin oxide

Triphenyltin

Fig. 5 Chemical structures of organotin fungicides

Organotin Compounds

Organotin compounds are formulated as wettable and flowable powders and are used throughout the world as fungicides in a variety of agricultural and industrial settings. Tributyltin oxide (TBTO) had been registered for use as an anti-mildew control agent in interior and exterior paints, but it is now severely restricted in many countries due to its potent irritant properties. TBTO continues to be used as an antifouling agent in marine paints, due to its ability to prevent the growth of barnacles, algae, and marine organisms.

Biochemistry and Pharmacokinetics

In general, organotin compounds have low water solubility and are lipophilic (Fig. 5). Toxicokinetic data in humans are not available [61].

Pharmacokinetics of Organotin

Volume of distribution: >1 L/kg

Protein binding: 80%

Mechanism of clearance: biliary, fecal

Active metabolite: trimethyltin

Methods to enhance clearance: none

Pathophysiology

TBTO is a potent skin irritant and an extreme eye irritant [62]. Triphenyltin compounds have been shown to induce irreversible ocular lesions in animal studies [61]. Immunotoxicity (lymphopenia, decreased spleen and thymus weights) and immunosuppressive effects (altered humoral and cellular immunity) have been described following organotin compound exposure in short-term and long-term animal studies [62]. These immunotoxic effects may arise from cytoskeletal modification in addition to alterations in thymocyte calcium homeostasis.

Clinical Presentation

Symptoms from inhalational exposure to interior paints with TBTO additives include headache, nausea, mucosal irritation, watery eyes, and wheezing [63]. Dermal exposure from direct contact with TBTO compounds has resulted in severe skin irritation, contact folliculitis, and pruritic erythematous vesiculobullous rashes [64, 65].

Reports of other systemic effects from accidental or intentional ingestion of organotin compounds are rare, and limited clinical information is available. In one case of intentional ingestion of triphenyltin acetate [66], a 19-year-old woman developed symptoms of vomiting, weakness, and nausea, followed by the development of diplopia, vertigo, bidirectional nystagmus, and disorientation. Leukopenia was noted on the sixth day postingestion. No other hematologic, renal, or hepatic abnormalities were found, and functional and radiographic studies of the CNS (including single-photon emission computed tomography and magnetic resonance imaging) were unremarkable except for nonspecific electroencephalogram changes. A full recovery was described with supportive management. A mass poisoning involving three deaths and hundreds of hospitalizations was reported in association with the misuse of industrial lard contaminated with organotin compounds as cooking oil [67]. Gas chromatography and k coupled plasma-mass spectrometry were used to detect and measure organotin species in blood and urine of exposed persons. Trimethyltin and dimethyltin were detected in urine samples at ng/mL concentrations. This report did not provide information on the clinical presentation and hospital course of the patients, which limits the utility of the biomarker findings.

Diagnosis

With inhalational and dermal routes of exposure, physical examination findings consistent with organotin exposure include skin and

mucous membrane irritation. In cases of systemic intoxication, gas chromatography and inductively coupled plasma-mass spectrometry may be used to detect and quantify organotin species in blood and urine specimens, although reference ranges have not been established. A complete blood count with differential may reveal lymphopenia as an immunotoxic manifestation of systemic organotin toxicity.

Treatment

Identification and removal from exposure and supportive management are the mainstays of therapy after exposure to organotin compounds. No data are available on the efficacy of gastric decontamination methods after accidental or intentional human ingestions. There are no animal studies on the efficacy of chelating agents in enhancing the elimination of organotin compounds, and there are no data supporting their efficacy in humans.

Indications for ICU Admission in Organotin Poisoning

Respiratory distress
Central nervous system depression

Criterion for ICU Discharge in Organotin Poisoning

Hemodynamic stability

Key Points in Organotin Poisoning

1. Organotin compounds are potent skin and mucosal irritants.
2. Immunotoxic effects have been described after acute systemic exposure.

Organophosphorus Insecticides

Organophosphorus (OP) insecticides are used widely in agriculture, horticulture, and veterinary medicine. These insecticides also are used domestically and in public hygiene to control vectors of disease. Some OP compounds (e.g., malathion) are used to treat human infestation with scabies, head lice, and crab lice.

As a result of the widespread use and availability of pesticides, each year 250,000–370,000 people die from their deliberate ingestion [1, 2]; these deaths are responsible for about a third of suicides globally [1]. The World Health Organization now recognizes pesticide poisoning to be the single most important means of suicide worldwide [3]. Many studies estimate that organophosphorus insecticides are responsible for around two-thirds of these deaths [4] – a total of some 200,000 a year [5].

Biochemistry and Clinical Toxicology

Biochemistry

Organophosphorus insecticides are usually esters, amides, or thiol derivatives of phosphoric acid (Fig. 1). The R¹ and R² moieties are usually alkyl or aryl groups, which may be linked via oxygen (this is termed a *phosphate*) (Fig. 1a) or a sulfur atom to phosphorus (when bonded via sulfur, the compound is called a *phosphorothiolate* or *S-substituted phosphorothioate*)

(Fig. 1b). When the phosphorus is linked by a double bond to sulfur ($P = S$), this is known as a *phosphorothioate* (Fig. 1c). *Phosphoramidates* (Fig. 1d) have a carbon atom linked to the phosphorus atom through an NH group.

The X in Fig. 1 represents one of a wide range of substituted or branched aliphatic, aromatic, or heterocyclic groups linked to the phosphorus atom via an -O- or -S- to make it more labile. During the process of inhibition of the target enzyme, acetylcholinesterase (AChE), the phosphorus atom binds to an amino acid on the enzyme with X being eliminated; the group X often is referred to as the “leaving group.” The lability of the linkage between X and the phosphorus atom is critical with regard to the reactivity of the OP with the enzyme AChE.

The $P = O$ -containing structure is often referred to as an *oxon*, and the $P = S$ structure is referred to

as a *thion*. The term *oxon* often is incorporated in the trivial name (e.g., parathion is the parent [$P = S$] compound of paraoxon [$P = O$]).

Clinical Toxicology

As most OP insecticides are lipophilic and not ionized, they are absorbed rapidly after inhalation or ingestion. Although dermal absorption of OP compounds tends to be slow, severe poisoning still may ensue if exposure is prolonged. The degree of absorption depends on the contact time with the skin, the lipophilicity of the agent involved, and the presence of solvents (e.g., xylene) and emulsifiers in the formulation, which can facilitate absorption. For powders, the finer the powder, the more rapid and complete is skin absorption. Other important factors include the volatility of the pesticide (e.g., dichlorvos is much more volatile than malathion, although both

Fig. 1 (a–d) Chemical structures of some organophosphorus insecticides

have relatively low vapor pressures), the permeability of clothing, the extent of coverage of the body surface, and personal hygiene. The rate of absorption also varies with the skin region affected. Parathion is absorbed more readily through the scrotal skin, axillae, and skin of the head and neck than it is through the skin of the hands and arms. Traumatized skin or the presence of dermatitis probably allows greater absorption of OP insecticides.

After absorption, OP compounds accumulate rapidly in the fat, liver, kidneys, and salivary glands. The phosphorothioates ($P = S$) (e.g., diazinon, parathion, and bromophos) are more lipophilic than phosphates ($P = O$) (e.g., dichlorvos) and are stored extensively in fat, which may account for the prolonged intoxication and clinical relapse after apparent recovery that has been observed in poisoning from these OP insecticides. This variable lipophilicity also explains why compounds vary in the ease with which they cross the blood–brain barrier.

Phosphates ($P = O$) are biologically active, whereas phosphorothioates ($P = S$) need bioactivation to the corresponding metabolite (oxon) to become biologically active. As a consequence, the features of intoxication may be delayed, unless aerial oxidation of the phosphorothioate ($P = S$) has occurred already to generate traces of oxon.

Organophosphorus compounds are metabolically activated to the corresponding oxon by oxidative desulfuration mediated by cytochrome P-450 isoforms [6], flavin-containing monooxygenase enzymes [7], *N*-oxidation, and *S*-oxidation [8]. The oxons that inhibit AChE can be deactivated by hydrolases, such as the carboxylesterases [9] and by A-esterases (e.g., paraoxonase). OP compounds undergo other transformations mediated by cytochrome P-450 that do not result in the production of an active metabolite, including oxidative dealkylation and dearylation [6]. OP compounds also may be transformed by enzymatic action on the side chains, including ring hydroxylation, thioether oxidation, deamination, alkyl and *N*-hydroxylation, *N*-oxide formation, and *N*-dealkylation [6]. The products of biotransformation may be

conjugated with glucuronide, sulfate, or glycine [10].

Elimination of metabolites occurs mostly in urine with lesser amounts in feces and expired air. Some OPs (e.g., dichlorvos, which is not stored in fat to any great extent) may be eliminated in hours, whereas the inhibitory oxon of chlorpyrifos or demeton-S-methyl may persist for days because of extensive storage in fat.

In summary, the chemical structure of the OP insecticides and the presence of other ingredients in the formulations may have an impact on the speed of onset of features of intoxication. In addition, the fact that many OP insecticides are lipophilic means that they are distributed to and stored in body fat, and elimination takes place slowly. The severity of intoxication may increase for 12–36 h after exposure, intoxication may be prolonged, or relapse may occur after apparent clinical recovery.

Pathophysiology of Toxic Effects

Acute Poisoning

The oxon phosphorylates the serine hydroxyl group located at the active site of AChE. Inhibition of AChE activity occurs in the blood, brain, and other tissues in a time-dependent manner. The extent of inhibition of AChE depends on the rate constant for the reaction and the time that the enzyme is exposed to the oxon. Inhibition of AChE results in accumulation of acetylcholine (ACh) at autonomic (both sympathetic and parasympathetic) preganglionic and some central synapses and at autonomic parasympathetic postganglionic and skeletal afferent nerve endings. Consequently, ACh binds to and stimulates muscarinic and nicotinic receptors. Phosphorylated enzyme may become “aged” by partial dealkylation of the serine group at the active site of AChE. “Aging” of the phosphorylated enzyme leads to an inactive enzyme, after which reactivation is no longer possible. The rate of aging depends on the structure of the OP compound. The activity of any aged, inhibited enzyme returns to normal only by resynthesis of new enzyme in the liver.

The rate of spontaneous reactivation of alkylphosphorylated AChE depends on the chemical structure of the OP compound. Most of the commonly used OP insecticides carry either two methyl (e.g., azinphos-methyl, demeton-S-methyl, dichlorvos, dimethoate, fenitrothion, malathion, oxydemeton-methyl, parathion-methyl) or two ethyl (e.g., chlorpyrifos, diazinon, disulfoton, ethion, parathion, quinalphos) ester groups attached to the phosphorus atom (see Fig. 1) so that dimethyl phosphorylated AChE or diethyl phosphorylated AChE is generated. The rate of spontaneous reactivation is faster for dimethoxyphosphoryl than diethoxyphosphoryl enzyme [11, 12], and this also appears to be true of oxime-induced reactivation [13]. Spontaneous reactivation of dimethoxyphosphorylated AChE proceeds quite rapidly so that the patient's condition should improve even without oxime therapy. Unless oximes are employed, however, there is no such expectation of rapid recovery for patients intoxicated with diethoxyphosphoryl insecticides.

OP-Induced Delayed Neuropathy

OP-induced delayed neuropathy is a rare complication of acute exposure to some OP insecticides [14–17]. It results from phosphorylation and subsequent aging of at least 70% of an esterase, neuropathy target esterase (NTE), in peripheral nerves that is distinct from AChE [18]; NTE is a 147 kDa membrane-bound protein of the patatin-like phospholipase family [19, 20]. After NTE becomes aged and as a result of loss of NTE activity, membrane phospholipid homeostasis and endoplasmic reticulum functions, including axonal transport and glial–axonal interactions, are disrupted [21]; axonal degeneration ensues and is followed by demyelination of nerve fibers [22]. Only a small number of marketed OP insecticides, for example, methamidophos [23], are capable of causing this syndrome, and most such OPs are banned. While there is compelling evidence of the involvement of NTE in the initiation of OP-induced delayed neuropathy, its role in axonal degradation remains obscure.

Intermediate Syndrome

Although the etiology of the syndrome is not clearly understood [24–30], it is generally believed to result from a persistent excess of ACh at the neuromuscular junction [31–39]. The intermediate syndrome can be regarded as a spectrum disorder affecting the neuromuscular junction: at one end of the spectrum, patients develop only the electrophysiological counterpart of neuromuscular transmission failure, while at the other end, patients develop weakness of three-fifths or less than three-fifths on the Medical Research Council grading of all three muscle groups and are at risk of developing respiratory failure [40]. The selective involvement of certain muscles remains unexplained.

Clinical Presentation and Life-Threatening Complications

Toxicity may occur after inhalation, after ingestion, or through skin contamination. Although dermal absorption of OP compounds tends to be slow, severe poisoning still may ensue if exposure is prolonged. Skin contact and subsequent absorption is the major route of exposure occupationally. Inhalation of OP insecticides, particularly during the manufacture of formulations (e.g., because of inefficiently operating ventilation equipment) or during spraying or mixing, is a recognized occupational hazard. Ingestion is uncommon in the workplace but can occur accidentally in workers with poor personal hygiene, such as those who do not remove contaminated clothing or fail to wash their hands. This exposure is likely to lead to only mild features, whereas the deliberate ingestion of an OP insecticide is likely to result in more severe features of intoxication.

The clinical presentation and severity of OP poisoning depends not only on the pesticide and the magnitude of exposure but also on several other factors, including the route of exposure, the age of the patient, whether exposure was a suicidal attempt (when a substantial ingestion is more likely), and the presence of a solvent in the formulation. Not only may skin absorption of the

Table 1 Systemic features of organophosphorus insecticide poisoning

Effect	Signs and symptoms
Muscarinic	Cough, wheeze, dyspnea, bronchorrhea, bronchoconstriction, pulmonary edema, cyanosis
	Rhinitis, increased salivation, rhinorrhea, increased lacrimation, diaphoresis, sweating
	Urinary and fecal incontinence
	Nausea, vomiting, abdominal cramps, diarrhea, tenesmus
	Bradycardia, hypotension
	Blurred vision, miosis
Nicotinic	Muscle fasciculation, including diaphragmatic muscle weakness
	Tachycardia, pallor
	Mydriasis
	Hyperglycemia
Central nervous system	Headaches, anxiety, dizziness, restlessness, insomnia, nightmares, drowsiness, confusion, tremor, ataxia, dysarthria, dystonic reactions
	Hypotension, respiratory depression
	Convulsions, coma

OP itself be enhanced by the presence of the solvent, but also ingestion of a solvent may induce vomiting with risk of aspiration; depressed consciousness may follow. There is increasing evidence that the solvents in formulations are responsible for the high morbidity and mortality [41, 42].

The onset and severity of toxicity depend on the speed and degree of depression of AChE activity. In addition, some OP compounds, such as the phosphorothioates, require biotransformation to become biologically active, and as a result, signs of intoxication may be delayed after exposure. Extensive occupational misuse of OP compounds may cause progressive depletion of AChE activity until toxic effects occur.

The typical features of OP poisoning are those of cholinergic excess and may be divided pharmacologically into muscarinic, nicotinic, and central nervous system effects (Table 1), though this classification is less relevant clinically except that it helps to explain the mechanisms of the features.

Table 2 Common *initial* features of OP insecticide poisoning by route of exposure

Route of exposure	Features
Inhalation	Chest tightness
	Rhinorrhea
	Increased salivation
Dermal	Bronchorrhea
	Localized sweating and muscle fasciculation
Ocular	Miosis
	Eye pain
Ingestion	Abdominal pain
	Nausea and vomiting
	Diarrhea
	Involuntary defecation

Note: systemic features may follow exposure by these routes

Symptoms can present within 5 min of massive ingestion and almost always occur within 12 h. Muscarinic symptoms rarely present more than 24 h after ingestion, although these features can reappear if therapy with oximes and atropine is discontinued too early. Muscarinic features appear first and characterize mild-to-moderate poisoning but are not always present. In one study, no single symptom was noted in more than 60% of cases [43]. Miosis, although the most prevalent specific sign, was found in only 44% of cases [43]. In other studies, miosis was observed in 82% of 61 cases [44] and in 83% of 23 cases [45].

The first symptoms of mild poisoning, particularly in individuals occupationally exposed, are often a feeling of exhaustion and weakness. Vomiting, cramping abdominal pain, sweating, and hypersalivation may follow (Table 2). Constriction of one or both pupils and a sensation of tightness in the chest during inspiration also may occur at an early stage, but these signs are not reliable indices of the severity of systemic poisoning because they may be caused by local anticholinesterase effects of spray mist on the eye or bronchi.

In cases of more severe poisoning, the nicotinic features tend to appear first, but a

combination of muscarinic, nicotinic, and central nervous system symptoms is apparent in many severe cases. This combination was found in 17% of patients in one series [43], although in a further study of more severely poisoned patients requiring ventilatory support, these features occurred in 60% [46].

Muscle twitching may affect the eyelids, tongue, face muscles, and calf muscles; respiratory muscles then become involved, and general muscle weakness ensues [47]. Convulsions may occur [45], though OPs vary in their potency to induce seizures [48]. Seizures may not be due entirely to AChE inhibition [49], considering that they are suppressed by benzodiazepines, which are known to act via 1-aminobutyric acidergic (GABAergic) mechanisms [50].

The respiratory complications of OP poisoning and their likely mechanisms have been reviewed [51, 52]. Bronchial hypersecretion/bronchorrhea with bronchoconstriction is followed in severe cases by cyanosis, respiratory depression, and coma. Death may follow from respiratory failure. Eddleston et al. [53] have proposed three mechanisms for respiratory failure occurring within a few hours of exposure during the acute cholinergic crisis: depression of the respiratory center in the ventrolateral medulla, respiratory muscle weakness, and direct pulmonary effects (bronchospasm, bronchorrhea). Bronchorrhea results from neuronal and nonneuronal cholinergic stimulation of the mucus glands, cilia, and cells producing periciliary fluid [52]. Bronchoconstriction results predominantly from bronchial smooth muscle contraction in response to muscarinic M3 receptor stimulation, with some involvement of nicotinic and M2 receptors (the latter also demonstrate negative feedback control); the nonspecific muscarinic antagonist atropine is highly effective in reversing bronchorrhea and bronchoconstriction. Respiratory failure may also occur later in conscious patients without cholinergic signs [53]. The mechanisms of late respiratory failure are uncertain, but some have suggested that the peripheral dysfunction results from sustained overstimulation of the neuromuscular junction by high synaptic concentrations of acetylcholine [54, 55]. Coma is usually due

Table 3 Cardiac manifestations of organophosphorus insecticide poisoning

to direct CNS depression by OPs and solvents in the commercial formulation, with EEGs show profound depression of cortical activity [56]. Aspiration pneumonia is common [57]. Other pulmonary function changes associated with OP poisoning include a decrease in dynamic lung compliance, an increase in total pulmonary resistance, and an alveolar–arterial oxygen gradient [58]. Respiratory effects generally are more severe in older patients with a history of respiratory disease.

Sinus tachycardia is likely to be present (although some patients may be bradycardic), but other cardiac effects (Table 3), including atrioventricular block, ST-segment changes, peaked T waves, and QT prolongation, have been observed. Ventricular arrhythmias are a common cause of death [59], and tachyarrhythmias of the torsades de pointes type [60, 61] may progress to ventricular fibrillation or asystole or both.

Mydriasis may be observed [62], particularly if atropine is given. Later effects may include diarrhea, tenesmus, incontinence, ataxia, and confusion.

Glycosuria and hyperglycemia [63, 64] have been reported. Leukocytosis and low-grade fever are noted frequently, even in the absence of infection. A low PaO₂ and metabolic acidosis are seen in severely poisoned patients, and creatine kinase activity may be high.

OP-Induced Delayed Neuropathy

Lotti and Moretto [14] have reviewed the features resulting from distal degeneration of some axons in both the peripheral and central nervous systems occurring 1–4 weeks after single or short-term exposures. Cramping muscle pain in the lower limbs, distal numbness, and paresthesias are followed by progressive weakness and depression of deep tendon reflexes in the lower limbs and, in severe cases, in the upper limbs. Signs include a high-stepping gait from bilateral foot drop and, in severe cases, quadriplegia with foot and wrist drop as well as pyramidal signs. In time, there might be significant recovery of peripheral nerve function, but, depending on the degree of pyramidal involvement, spastic ataxia may be permanent [14]. Human and experimental data indicate that recovery is usually complete in the young.

Intermediate Syndrome

Relapse after apparent resolution of cholinergic symptoms has been reported, particularly in patients who have ingested highly lipophilic OP insecticides, and is termed the intermediate syndrome. The syndrome was first described by Senanayake and Karalliedde [54] who reported the onset of muscle paralysis affecting particularly upper limb muscles, neck flexors, and cranial nerves some 24–96 h after OP exposure, though there are reports of paralysis occurring before 24 h and even after 96 h [31, 53, 65]. It is often associated with the development of respiratory failure, a major contributor to the high mortality of OP poisoning. Several recent reviews have described the syndrome in detail [40, 66–68].

Jayawardane et al. [40] have shown that subclinical electrophysiological abnormalities are common, progressive, and precede the onset of the clinical syndrome. Serial repetitive nerve stimulation studies have been most commonly used and are the most accessible for clinicians. Clinical and experimental studies demonstrate a progression through early initial decrement–increment patterns at high rates of stimulations, which correlate with moderate muscle weakness, to decrement–increment patterns at intermediate- and low-frequency stimulations. Progression to a

combination of decrement–increment and repetitive fade patterns correlates with clinical deterioration. Severe decrement pattern is usually observed immediately before the onset of respiratory failure. Although electrophysiological features closely parallel clinical severity during progression of the syndrome, the same is not true during recovery. Electrophysiological changes sometimes improve long before the patient recovers normal strength and respiratory function.

Delayed Neuropsychological Sequelae After OP Poisoning

Since acute poisoning with OP insecticides can cause major effects such as convulsions, respiratory failure, and cardiac arrhythmias, all of which can result in cerebral anoxia, it would not be surprising if severe acute OP poisoning was associated with long-term neurological sequelae. Moreover, there is now evidence that such complications can occur [69]. However, shortcomings in the methodology of these studies, including poor assessment of exposures and of the severity of poisoning, different timing of examination after poisoning, and choice of controls, do not allow a firm conclusion to be drawn that severe acute OP poisoning can produce subclinical damage to the central and peripheral nervous systems.

Rosenstock et al. [70] and McConnell et al. [71] investigated the neurophysiological effects and, as an index of delayed neuropathy, measured vibrotactile thresholds in 36 male agricultural workers in Nicaragua who had been admitted to hospital between 10 and 34 months earlier with occupationally related acute OP poisoning; 21 of 36 workers had been poisoned with methamidophos, a recognized peripheral neurotoxin. In a battery of neuropsychological tests, the exposed group performed significantly worse than the control group, and a significant decrease in vibrotactile sensitivity was also observed.

Steenland et al. [72] studied 128 men exposed to OP insecticides, the majority, occupationally, who had sought medical attention and of whom 28% had been admitted to hospital in California for more than one night. Neurobehavioral tests, nerve conduction tests, and vibrotactile threshold

responses were undertaken several years after exposure. The study group performed significantly worse in tests of sustained visual attention and mood, and those in the “definitely” poisoned subgroup also showed significantly worse vibrotactile sensitivity of the finger and toe, but had no neurological symptoms.

Savage et al. [73] investigated the presence of chronic neurological or neuropsychological abnormalities in 100 subjects who had experienced at least one episode of acute OP poisoning confirmed by a physician. The authors found significant deficits in a wide range of neuropsychological variables, including visuomotor, attention, and language function. Persistent abnormalities in affective behavior, especially anxiety, were also found, though no differences on EEG or neurological examination were identified.

Miranda et al. [74] studied a cohort of men who were exposed predominantly occupationally to an OP insecticide and who had been admitted for at least 1 day to two hospitals in Nicaragua for treatment of OP poisoning. Quantitative tactile vibration thresholds were measured in 56 subjects on the first occasion 1–24 days (median 7) after exposure and for the second time 24–128 days (median 50) after poisoning and compared to 39 nonexposed men. Big-toe vibrotactile thresholds increased markedly from the first to the second examinations in those with severe intentional poisoning (ingestion) due to neuropathic OPs (methamidophos, chlorpyrifos). No significant impairment of vibrotactile thresholds was detected in association with occupational poisonings or with less severe intentional poisonings with neuropathic or non-neuropathic OPs.

In a second study [75] of the same Nicaraguan population ($n = 59$), marked impairment of grip and pinch strength in the dominant hand was found, particularly among those with severe poisoning due either to neuropathic OPs or intentional ingestion.

In a third study [76], hand strength and vibration thresholds were performed in 48 men 2 years after admission for acute OP poisoning. In those exposed to non-neuropathic OPs, grip and strength had recovered and was not different from controls; pinch strength remained lower

than for controls. Those only moderately poisoned with neuropathic OPs poisoning showed an evolution similar to those exposed to non-neuropathic OPs, whereas those severely poisoned (notably as a result of intentional ingestion) still remained significantly weaker than controls. Index finger and toe vibration thresholds were slightly increased at the end of the 2-year period.

In a fourth study [77] in 53 individuals, changes in immediate verbal memory, visuomotor performance, and neuropsychiatric symptoms at the time of discharge, at 7 weeks post poisoning, and at 2 years were evaluated. Immediate verbal learning showed deficits in the high exposure group, particularly at the time of discharge. Visuomotor performance showed a deficit at 7 weeks but improved thereafter. A 2-year delayed excess of neuropsychiatric symptoms was present in those occupationally exposed. The authors concluded that visuomotor performance and possibly short-term verbal memory were affected early after severe acute OP poisoning and recover, either truly or by some compensatory mechanism. Neuropsychiatric symptoms seemed to increase after a longer latent period, particularly in the less severely exposed subjects.

Neuropsychological Effects Following Low-Level OP Exposure

There remains controversy as to whether low-level exposures to OP insecticides (without the features of acute poisoning or the cholinergic syndrome having occurred) can result in peripheral nerve dysfunction. However, we are still of the view [78], first proposed by Lotti [79], that a single pattern of subclinical disturbances that relates low-level OP exposure to human peripheral neuropathy has not been identified. The clinical characteristics of the mild neuropathies described point to a condition that differs from OP-induced delayed polyneuropathy. The distribution of involved peripheral nerves is unusual for a toxic polyneuropathy, including OP-induced delayed neuropathy, because both upper and lower limbs seem to be affected at once. In some studies, defects seem irreversible, because they were detected several months after cessation of exposure. Although OPs are rapidly cleared from

the body and peripheral nerves regenerate, it is not clear what mechanism would sustain a peripheral neuropathy for a sustained period of time after cessation of exposure. Therefore, in the absence of histopathology and follow-up studies, the significance of these changes remains unclear. These difficulties in interpretation are further amplified by the lack of an experimental model other than the classic OP-induced delayed polyneuropathy one. These mild, inconsistent and unexplained findings provide no evidence to support the proposal that low-level exposures to OPs caused peripheral neuropathy in humans, even among possibly hypersusceptible individuals.

As regards neurobehavioral function after low-level OP exposure, Mackenzie Ross et al. [80], having reviewed the available evidence by conducting a meta-analysis of 14 studies involving more than 1600 participants, claimed to have found a significant association between “low-level exposure to OPs and impaired neurobehavioral function which is consistent, small to moderate in magnitude and concerned primarily with cognitive functions such as psychomotor speed, executive function, visuospatial ability, working and visual memory.”

Diagnosis

The diagnosis of OP poisoning is based on the patient's history, clinical presentation, and laboratory tests. In a patient with a positive history, a typical odor on the breath, characteristic symptoms, and depressed erythrocyte and plasma cholinesterase activities, diagnosis is not difficult to make. The history is often unobtainable and in one study was missing in 36% of all cases [81]. The clinical features of OP poisoning may not be recognized as such if the patient presents, for example, with heart block, gastroenteritis, convulsions, or ketoacidosis. An awareness of this diversity of presentation is the first step toward accurate diagnosis. If there is a doubt regarding the diagnosis, consultation with a medical toxicologist or poison center should be considered.

The activity of two enzymes may be measured to confirm a diagnosis of OP poisoning. These are

red cell AChE and plasma butyrylcholinesterase (plasma cholinesterase, plasma pseudocholinesterase, BuChE). Both are surrogates for AChE activity in the central and peripheral nervous systems. The erythrocyte AChE activity is invariably more specific than plasma butyrylcholinesterase activity as a marker of OP insecticide exposure, though some OP insecticides (e.g., chlorpyrifos, demeton, malathion) depress plasma butyrylcholinesterase activity to a greater degree than erythrocyte cholinesterase activity. The diagnosis of OP poisoning can be confirmed by showing a significantly reduced cholinesterase activity in red blood cells or plasma, preferably the former. Difficulty often arises regarding the interpretation of results of plasma cholinesterase activities because individuals can vary widely in their normal complement of plasma cholinesterase. Low plasma cholinesterase activity should be confirmed by the measurement of red blood cell cholinesterase activity.

Usually a good correlation exists between the activity of erythrocyte AChE and the severity of symptoms in OP poisoning [82]. Hence, it is not necessary to wait for confirmation from the laboratory for the diagnosis of acute OP poisoning to be confirmed; specific treatment should be started immediately.

Few laboratories can determine quantitatively the insecticide responsible for the intoxication and measurement of the parent compound or metabolite in body fluids. Such measurement has little place in the immediate diagnosis or early management of poisoning. In many cases, rapid hydrolysis prevents the detection of the parent compound, although urinary metabolites may persist for several days. The measurement of metabolites is most helpful as a measure of low-level chronic exposure.

Treatment

All cases of OP poisoning should be dealt with as an emergency, and all patients with more than minor symptoms (grade 2 or greater, see Table 4) should be admitted to a critical care unit. Given the effects of OPs on the respiratory system,

Table 4 Assessment of severity and management of severe organophosphorus insecticide poisoning (After Johnson and Vale [98])

Grade 0	Suggestive history but no features of intoxication present
Grade 1	Patient is alert and awake and has
	Increased secretions
	Fasciculation +
Grade 2	Patient is drowsy and has
	Severe bronchorrhea
	Fasciculations + + +
	Crackles/wheezes on auscultation
	Hypotension (systolic BP <90 mm Hg)
Grade 3	Patient is comatose and has all the features of severe intoxication
	Increased FiO ₂ needed but not mechanical ventilation
Grade 4	Patient is comatose and has all the features of severe intoxication
	PaO ₂ < 8 kPa (60 mm Hg) despite FiO ₂ > 40%; PaCO ₂ > 6 kPa (45 mm Hg)
	Mechanical ventilation required
	Abnormal chest radiograph (circumscribed or diffuse opacities, pulmonary edema)

Note: all patients \geq grade 2 should be admitted to an intensive care unit

particular attention should be directed toward the patient's ventilatory status. Bronchorrhea requires prompt relief with intravenous atropine (see later), and supplemental oxygen should be given to maintain PaO₂ greater than 8 kPa (60 mm Hg). If these measures fail, the patient should be intubated, and mechanical ventilation (with positive end-expiratory pressure) should be instituted. Careful attention must be given to fluid and electrolyte balance and adjustments to infusion fluids made as necessary. Heart rate, blood pressure, electrocardiogram, and arterial blood gases should be monitored routinely.

Decontamination

During and after stabilization, thorough skin decontamination should be carried out, without caregivers themselves being contaminated. All contaminated clothing should be removed, and affected skin on all exposed areas should be washed thoroughly with soap and cold water (e.g., hands, arms, face, neck, and hair).

Gastric lavage has no routine role in management even after substantial ingestion of an OP insecticide as its value is unproven and its execution is potentially dangerous because hydrocarbons are present in many OP insecticide formulations.

The capacity of activated charcoal to adsorb most OP compounds has not been shown. While on theoretical grounds the use of activated charcoal might be considered, in a large study in Sri Lanka, involving OP and carbamate insecticide poisoning, no benefit from single- or multiple-dose charcoal was demonstrated [83]. Patients were randomized to receive no charcoal ($n = 1554$), one dose of charcoal 50 g ($n = 1545$), or six doses of charcoal 50 g at 4 h intervals ($n = 1533$); outcomes were available for 4629 patients. 2338 (51%) individuals had ingested pesticides (1310 had ingested OP and carbamate insecticides), whereas 1647 (36%) had ingested yellow oleander (*Thevetia peruviana*) seeds. Mortality did not differ between the groups: 109 (7.1%) of 1544 participants in the single-dose charcoal group died (adjusted odds ratio 1.05, 95% CI 0.79–1.40); 97 (6.3%) of 1531 participants in the multiple-dose charcoal group died (adjusted odds ratio 0.93, CI 0.69–1.25), compared with 105 (6.8%) of 1554 in the no charcoal group. No differences were noted for patients who took particular poisons, were severely ill on admission, or who presented early. Level of evidence for charcoal use in decontamination is therefore grade IV.

Supportive Care

In severely poisoned patients who are hypotensive, it may be necessary not only to expand plasma volume by administering a bolus of intravenous crystalloid but also to give inotropic support. Cardiac arrhythmias should be treated conventionally, and hypoxia must be considered as a possible etiology. The management of convulsions and muscle fasciculation is discussed later.

Antidotes

The evidence base for atropine, oximes, and diazepam has been reviewed [84–86]. While the

therapeutic combination of oxime and atropine is well established in experimental OP pesticide poisoning and is used routinely clinically, diazepam may also be of benefit by reducing anxiety, restlessness, and muscle fasciculation, suppressing seizures, and reducing morbidity and mortality when used in conjunction with an oxime and atropine.

Atropine

Atropine antagonizes the effects of accumulated ACh at muscarinic receptors. Atropine sulfate 2 mg (0.02–0.1 mg/kg in a child) intravenously should be given as soon as possible in moderately and severely poisoned adults and may be lifesaving in those with rhinorrhea and bronchorrhea (Grade I recommendation). The atropine dose should be titrated to control rhinorrhea and bronchorrhea, to raise the pulse rate above 80 bpm, and restore systolic blood pressure to more than 80 mmHg. In severe cases, several hundred milligram may be required, though in a study in Sri Lanka the mean dose was 23.4 mg (standard deviation 22.0, range 1–75 mg) [87]. If the initial dose produces only a partial response, it should be doubled and doubled again if there is only a limited clinical response [87].

An open-label randomized clinical trial was conducted in Chittagong Medical College Hospital, Chittagong, Bangladesh, on 156 hospitalized individuals with OP insecticide poisoning from June to September 2006 [88]. Group A consisted of 81 patients who received conventional bolus-dose atropine (increasing doses of intravenous atropine from 2 to 5 mg depending on severity, as assessed by the treating clinician, and repeated every 10–15 min until signs of atropinization were clinically evident); Group B consisted of 75 patients who received rapidly incremental doses of atropine (a first dose of 1.8–3.0 mg depending on severity as assessed by the treating clinician followed by another 5 min later at double this dose if needed. This was repeated every 5 min until all clinical signs of atropinization were clearly evident) followed by an atropine infusion (10% of the atropine required to load the patient was given per hour [e.g., if atropine required for atropinization was 18 mg, 1.8 mg was infused

each hour]). The mortality in Group A was 22.5% (18/80) and in Group B 8% (6/75) ($p < 0.05$). The mean duration of atropinization in Group A was 151.74 min compared to 23.90 min for Group B ($p < 0.001$). More patients in Group A experienced atropine toxicity than in Group B (28.4% vs. 12.0%, $p < 0.05$); intermediate syndrome was more common in Group A than in Group B (13.6% vs. 4%, $p < 0.05$), and respiratory support was required more often for patients in Group A than in Group B (24.7% vs. 8%, $p < 0.05$). In this study, rapid incremental dose atropinization followed by an atropine infusion reduced mortality and morbidity and shortened the length of hospital stay and recovery.

The peripheral antimuscarinic effects of atropine may not be the only antidotal property of the drug; it may also be of value in treating the acute dystonic reactions observed occasionally [89–92].

Oximes

The fundamental action of the pyridinium oximes is to reactivate AChE inhibited by OPs (see Fig. 52.3), thus allowing ACh to be hydrolyzed in the usual way and resumption of normal cholinergic neurotransmission (see also ► Chap. 52, “Hydantoin Anticonvulsants: Phenytoin and Fosphenytoin”). Pralidoxime does not pass readily into the central nervous system [93] because of its quaternary nitrogen structure. There are numerous contradictory reports of animal experiments showing occasionally detectable oxime concentrations in the brain and cerebrospinal fluid [94]. In the main, oxime doses far beyond those administered to humans were used, and the positive assays in the brain tissue may reflect damage to the blood–brain barrier rather than natural permeability to oximes [94]. All these data indicate that while the blood–brain barrier is not entirely impermeable to quaternary pyridinium compounds, it may become more permeable in stress situations, such as in severe intoxication [94].

It is generally held that the beneficial effects of pyridinium oximes in OP poisoning are confined to peripheral nicotinic sites and that peripheral muscarinic and central nervous effects are clinically insignificant. Thus, the beneficial effects of

oximes are mainly on neuromuscular transmission, and there is little action on muscarinic parasympathetic effects such as bronchorrhea, bronchoconstriction, and rhinorrhea. As atropine acts largely at peripheral muscarinic sites, the therapeutic combination of oxime and atropine is well established in the treatment of organophosphorus insecticide poisoning.

The reactivation of inhibited AChE and clinical improvement depend on:

- (i) The chemical form of inhibited AChE. While spontaneous reactivation of dimethyl phosphorylated AChE proceeds rapidly, in the case of diethyl phosphorylated AChE, it is very slow. Spontaneous reactivation of diethyl phosphorylated AChE can be accelerated by oximes.
- (ii) The plasma concentration of the OP insecticide [95, 96].
- (iii) Aging which results from monodealkylation of dialkoxylphosphorylated AChE [97]; aged enzyme reactivates neither spontaneously nor under the influence of oximes so that recovery depends on synthesis *de novo* of more enzyme.
- (iv) The plasma oxime concentration.
- (v) The duration of oxime therapy.

It is commonly but erroneously believed that within 1 day of intoxication, virtually all the inhibited AChE is in the “aged” form so that oxime therapy, if employed, would be useless. There are good biochemical reasons, however, for suggesting that as soon as an effective concentration of oxime is achieved *in vivo*, the balance of aging and reactivation reaction rate for inhibited AChE is altered in favor of the latter [98]. Progress toward complete inhibition may be slowed markedly. It is probable that benefit would ensue even if oxime therapy was started or continued several days after intoxication occurred [99].

There are consistent animal data supporting the effectiveness of oximes, when given early [100–107]. There are also some clinical studies which support the benefit of oxime therapy. Pawar et al. [108] administered two pralidoxime-dosing schedules in 200 patients who had moderately

severe OP insecticide poisoning. Patients ($n = 100$) who received the high-dose regimen (pralidoxime iodide 2 g loading dose over 30 min, then 1 g/h for 48 h, and then 1 g every 4 h until weaned from the ventilator) had a lower mortality (1% vs. 8%; $p = 0.03491$), less need of intubation ($p = 0.0001$), and a shorter time on ventilator support ($p < 0.0001$) than the 100 patients receiving a lower-dose regimen (pralidoxime iodide 2 g loading dose, then 1 g every 4 h until weaned). Those receiving high-dose pralidoxime also developed less muscle weakness and required less atropine (median 6 mg vs. 30 mg; $p = 0.0001$) during the first day and fewer developed pneumonia ($p < 0.0001$).

In contrast, de Silva and colleagues [109] concluded that nothing is to be gained in cases of severe acute OP insecticide poisoning by the addition of oxime reactivators to the standard regimen of atropine plus mechanical ventilation. This conclusion, which has been challenged [110], was based on a study in which 21 patients received atropine alone and 24 patients received atropine plus pralidoxime chloride (median doses, 4 g in the first 24 h and 1 g daily thereafter). The mortality in both groups was 29%, which is not dissimilar to that reported from other centers managing severe cases of OP insecticide poisoning.

Eddleston et al. [111] came to a similar conclusion after performing a double-blind, randomized, placebo-controlled trial comparing pralidoxime chloride (2 g loading dose, followed by a constant infusion of 0.5 g/h for up to 7 days) with saline. Despite clear reactivation of red cell AChE activity in diethyl OP pesticide-poisoned patients, there was no evidence of improved survival or reduced need for intubation [111].

The value of oximes has also been challenged in a Cochrane Review [86] which concluded that

Current evidence is insufficient to indicate whether oximes are harmful or beneficial in the management of acute OP pesticide poisoning. The World Health Organization recommended pralidoxime regimen (30 mg/kg pralidoxime chloride bolus followed by 8 mg/kg/h infusion) is not supported by outcomes to date. Lower doses have also shown worse outcomes in one RCT. Thus the published RCTs provide limited guidance for clinicians. Despite this there are consistent animal data supporting their

effectiveness, when given early. Based on our understanding of the mechanism, *in vitro* and animal data, benefit–risk ratio is more likely to be favorable when they are given early, to patients with serious poisoning by diethyl OPs. However, the RCTs have not defined effective doses or subgroups that are likely to benefit.

Specifically, the Cochrane Review [86] identified seven RCTs (845 people) in those poisoned with OP insecticides. Three of the RCTs (366 people), reported in four publications [111–114], compared pralidoxime treatment with placebo and the outcomes of mortality and ventilation requirement. Reporting of methods in the RCTs was poor. The review noted that many studies did not account for factors that would affect outcomes. In some studies, characteristics of participants in different groups were not balanced at baseline. Only one RCT [111], comparing pralidoxime treatment with placebo, used doses of pralidoxime recommended by the World Health Organization (at least 30 mg/kg loading dose, then 8 mg/kg/h intravenous infusion) [115, 116].

In the three RCTs, oximes were given either as a dose of 4–12 g infused daily over 3 days without a loading dose or as a 2 g loading dose over 20 min followed by a constant infusion of 0.5 g/h for a maximum of 7 days. The review found no significant difference between treatment with an oxime and placebo in mortality (3 RCTs = 366 people; 47/186 [25%] with oxime treatment vs. 22/180 [12%] with placebo; OR 2.68, 95% CI 0.93–7.72) or need for ventilation (3 RCTs = 70/186 [38%] with oxime treatment vs. 50/180 [28%] with placebo; OR 2.00, 95% CI 0.81–4.95). The review authors noted that the different oxime doses used in the studies and differences in the types of organophosphate poison meant that meta-analysis might not produce a true estimate of effect. One of the RCTs (110 people) identified by the review also reported the proportion of people developing intermediate syndrome [113, 114]. It found that an infusion of pralidoxime 12 g over 3 days significantly increased the proportion of people developing intermediate syndrome compared with placebo (36/55 [65%] with pralidoxime vs. 19/55 [35%] with placebo; OR 3.59, 95% CI 1.64–7.88). However, baseline differences in this RCT suggested that people

allocated to treatment with an oxime might have been more severely poisoned compared with those allocated to placebo [86].

Why is there this discrepancy between the experimental and clinical data? In an important study performed in mini pigs using orally administered clinically relevant doses of dimethoate EC (agricultural emulsifiable concentrate), dimethoate active ingredient alone, or solvents, Eddleston et al. [42] found that administration of agricultural dimethoate EC, but not saline, caused respiratory arrest within 30 min, severe distributive shock, and NMJ dysfunction, that was similar to human poisoning. Moderate toxicity resulted from poisoning with dimethoate active ingredient alone or the major solvent cyclohexanone. Combining dimethoate with cyclohexanone reproduced severe poisoning characteristic of agricultural dimethoate EC poisoning. A formulation without cyclohexanone showed less mammalian toxicity. These results indicate that solvents play a crucial role in OP (and specifically dimethoate) toxicity, which could explain why oximes seem to be less effective clinically than in experimental studies where pure OP insecticide rather than marketed formulations is often employed.

Pralidoxime

Pralidoxime chloride 30 mg/kg by intravenous injection should be administered as soon as possible in any severe or progressive case of intoxication and repeated at 4–6-h interval; alternatively an intravenous infusion of 8–10 mg/kg/h in an adult may be employed. These regimens are based on reported clinical studies [95, 117, 118] and have been recommended by WHO [115] and ourselves [119]; these are Level III recommendations. Administration of pralidoxime should continue for as long as atropine is required, that is, until clear, irreversible clinical improvement is achieved, which may take many days, while residual insecticide is cleared from the body stores.

Obidoxime

Based on pharmacokinetic data of obidoxime in healthy human volunteers [120], Thiermann et al. [121] considered that a bolus dose of obidoxime 250 mg IV, followed by a continuous

infusion at 30 mg/h, is an appropriate therapeutic regimen, which they employed in single patients [122, 123]; this is a Level III recommendation. The efficacy and safety of this regimen was evaluated in an observational study [124, 125]. These authors further investigated this regimen in 34 severely poisoned patients [121]. The mean (\pm SD) total dose of obidoxime infused over 65 (\pm 55) h was 2,269 (\pm 1,726) mg, which resulted in a mean steady-state plasma concentration of 5.2 (\pm 2.6) mg/L. Reactivation of inhibited erythrocyte AChE was achieved in 23 of 34 patients, while in seven patients, aging was complete before the commencement of obidoxime. In four patients high OP insecticide load prevented significant reactivation, and complete aging ensued in spite of this obidoxime regimen.

Thiermann et al. [123] reported that in parathion poisoning, obidoxime 250 mg IV as a bolus followed by 750 mg/day by infusion was effective but that in severe poisoning AChE reactivation did not occur until the concentration of inhibitor in the plasma had declined. The same dosage regimen was ineffective with oxydemeton-methyl when oxime therapy was delayed more than 1 day after poisoning. In another series, Thiermann et al. [126] reported that in parathion poisoning, reactivation was possible 7 days after poisoning, whereas with oxydemeton-methyl, a response was only seen when obidoxime therapy was instituted soon after poisoning. Similarly, Zilker et al. [127] found that obidoxime (750 mg/day by infusion) reduced the need for atropine in parathion poisoning but that demeton-S-methyl poisoning only responded if obidoxime therapy was instituted shortly after intoxication.

Adverse Effects of Oximes

Male volunteers were given obidoxime 1.84–3.58 g as a single dose, or 7.36 g divided into 4 equal doses. Over half the subjects complained of one or more side effects: pallor, nausea, burning sensation, headache, generalized weakness, sore throat, and paresthesia of the face. However, activities of blood cholinesterase, alanine, and aspartate aminotransferases, as well as hematocrit values, heart rate, and blood pressure were not affected [128].

In human volunteer studies, Jager and Stagg [129] found that medical students given pralidoxime iodide developed dizziness, blurred vision, diplopia, impairment of accommodation, and headache. Dizziness, blurred vision, and occasionally diplopia have been reported in human volunteer studies after intravenous or intramuscular administration of pralidoxime chloride [130].

Reversible fatty change has been observed in the liver of rats dosed with obidoxime [131], and impaired liver function has been seen in humans after treatment of parathion poisoning treated with obidoxime [132, 133]. Finkelstein et al. [46] have shown an association between liver dysfunction and the cumulative dose of obidoxime. The liver damage usually manifests as an increase in hepatic enzyme activities and hyperbilirubinemia [123].

Diazepam

Diazepam may be of benefit in OP-poisoned patients by:

1. Reducing anxiety and restlessness
2. Reducing muscle fasciculation
3. Treating seizures
4. Reducing morbidity and mortality when used in conjunction with pralidoxime and atropine

Diazepam 10 mg intravenously reduces anxiety, restlessness, and visible motor activity. Midazolam has been employed as an alternative benzodiazepine but offers no advantages over diazepam in this regard. Short-term diazepam, 10–20 mg (or midazolam 10 mg, then 10 mg after 10 min if required) in an adult, is also an effective anticonvulsant and may prevent chronic OP-induced seizures if administered immediately [134]. Potentially, respiratory depression may result from the repeated use of a benzodiazepine, although this is unlikely to be a significant clinical problem, unless OP-induced respiratory impairment also is present and the patient is breathing spontaneously. If repeated doses of a benzodiazepine are required to suppress seizure activity, phenytoin is an appropriate second-line agent as it has been shown *in vitro* to be an effective anticonvulsant (suppression of epileptiform bursting in

guinea-pig hippocampal slices induced by the OP nerve agent, soman) [135]. Phenytoin 20 mg/kg (max. per dose 2 g) should be given at a rate not exceeding 1 mg/kg/min (max. 50 mg/min), with blood pressure and ECG monitoring.

Prevention and Treatment of Intermediate Syndrome

If intermediate syndrome is a consequence of ACh accumulation at the neuromuscular junction, oximes should protect against its development. It is noteworthy, and possibly relevant, that pralidoxime methylsulfate protected against development of muscle fiber necrosis [136]. Johnson et al. [137] reported a prospective trial with two treatment regimens of pralidoxime in the treatment of patients with OP poisoning. Seventy-two adults with a history of consumption of these compounds and requiring intensive care were entered into the trial. They were then randomized using a block randomization to receive either a single bolus of pralidoxime 1 g at admission followed by placebo infusion over the next 4 days or a single placebo bolus at admission followed by pralidoxime 12 g as a continuous infusion over the next 4 days. A higher prevalence of intermediate syndrome was observed in the latter group. Comparison of patients who received at least pralidoxime 1 g within 12 h of ingestion of the OP poison with those who received pralidoxime after 12 h suggested that the time of administration of pralidoxime was important, the first group being less likely to develop the syndrome.

However, other case reports have suggested that high dose of oxime may not avert intermediate syndrome. In a case of severe malathion self-poisoning, pralidoxime 1 g was administered intravenously approximately 7 h after poisoning, and at 12 h, an infusion of pralidoxime 400 mg/h was given. The patient developed intermediate syndrome on hospital day 3 [138].

Carbamate Insecticides

Carbamate insecticides were developed in the 1950s in response to a search for insecticides with anticholinesterase activity but with greater

specificity and lower mammalian toxicity than OP insecticides. Carbamates are used widely in many countries where agriculture is a major industry and pest control essential and are employed frequently as alternatives to OP insecticides. Carbamate insecticides include carbaryl, aldicarb, methomyl, carbofuran, bendiocarb, benfuracarb, butoxycarboxim, carbosulfan, ethiofencarb, methiocarb, oxamyl, pirimicarb, propoxur, thiodicarb, and thiofanox.

Poisoning with carbamates almost always involves commercial formulations, not isolated active ingredients, and the additional chemicals they contain not infrequently contribute to toxicity [139–142]. Carbamate poisoning occurs predominantly in countries where agriculture is the primary industry, and pesticide ingestion is an important means of suicide. Among 228 confirmed fatal poisonings in Northern Greece between 1990 and 1995, carbamates were implicated in 24 of 85 cases of pesticide poisoning [143]. There have been occasional outbreaks of carbamate poisoning after consumption of contaminated food [144, 145] or illegal use as a rodenticide [146] and as the poison in attempted murder [147].

Biochemistry and Clinical Pharmacology

Carbamate insecticides are derivatives of *N*-methyl carbamic acid and have the general formula $\text{CH}_3\text{NHC(O)OR}$, where R is an aromatic or aliphatic moiety. Carbamate insecticides are susceptible to hydrolysis in alkalis, a property that is used in decontamination and cleanup after carbamate spillages.

Clinical Pharmacology

Carbamate insecticides are lipophilic and absorbed readily by dermal and inhalational exposure and after ingestion. The use of these agents in conditions of high temperature and humidity enhances dermal absorption because of increased exposed skin surface area and peripheral vasodilation. In addition, in high ambient temperatures, some carbamate aerosols (e.g., propoxur) are

susceptible to revolatilization with increased likelihood of absorption by inhalation.

When absorbed, carbamate esters undergo rapid biotransformation via phase I and phase II detoxification reactions. Phase I detoxification involves either hydrolysis of the carbamate ester by nonspecific tissue carboxylesterases (to form a phenol or alcohol, carbon dioxide, and an amine) or oxidation by monooxygenase P-450 enzymes. Oxidative reactions predominantly involve either direct ring hydroxylation or side-chain oxidation reactions (e.g., *N*-dealkylation or *O*-dealkylation or *N*-methyl hydroxylation). Phase II conjugative reactions produce sulfates, glucuronides, and mercapturates of the hydrolysis products. These species are eliminated predominantly by the kidneys. Based on the limited data available, the plasma half-life of carbamate insecticides is of the order of a few hours [148]. A woman who ingested 10 g of aldicarb developed severe poisoning with a peak serum aldicarb concentration at 3 h. The aldicarb plasma half-life in this case was 5.75 h [149].

Pathophysiology of Toxic Effects

Carbamates inhibit AChE by carbamylation of a serine hydroxyl residue at the active site of the enzyme. This process involves cleavage of the carbamate molecule, which in effect is treated by the enzyme as an alternative substrate to ACh [150]. The AChE–carbamate interaction is not truly reversible because the carbamate does not depart the encounter intact, but rather as the products of hydrolysis. AChE activity is restored when spontaneous hydrolysis of the carbamylated enzyme occurs. This spontaneous reactivation of carbamylated enzyme, expressed as half-life, varies between 2 and 240 min depending on the carbamate and in part explains some of the observed differences between carbamates as regards their toxicity [148]. The rate of regeneration of the carbamylated enzyme to AChE is relatively rapid compared with that of an OP-phosphorylated enzyme, and aging does not occur. Many carbamates do not cross the blood–brain barrier readily, so the impact on

cerebral AChE is considerably less than that caused by OP insecticides. For all these reasons, human exposure to carbamate insecticides is potentially less dangerous than exposure to an OP insecticide.

Clinical Presentation and Life-Threatening Complications

Toxicity may occur after inhalation, ingestion, or skin contamination. Inhalational and topical exposures typically are occupational. Life-threatening poisoning in these circumstances is rare, although cholinergic symptoms have occurred after equipment malfunction or inadequate protective measures [151–153]. In these cases, the rapid (often within 30 min) onset of mild cholinergic features, including nausea, headache, sweating, lacrimation, salivation, chest tightness, coughing, bronchorrhea, and constriction of one or both pupils causing blurred vision, serves to alert affected individuals to remove themselves from exposure [151, 152, 154]. Resolution of symptoms occurs typically within hours [154], often without the need for atropinization [152]. If exposure continues, vomiting, diarrhea, abdominal pain, muscle fasciculation, and weakness develop [152]. Hypotension, sinus tachycardia or bradycardia, and dyspnea also may occur [152]. Electrocardiogram T-wave changes, including inversion, are recognized [155]. Severe sequelae after occupational carbamate exposure are rare, often involve methomyl, and include several cases involving pilots of crop-spraying aircraft exposed to carbamates in the cockpit [156–158]. One of these cases [157] proved fatal as a result of the pilot crashing the plane.

Most cases of severe carbamate poisoning occur after ingestion, which may be accidental [146, 159] or deliberate [146, 160, 161]. These patients usually develop cholinergic symptoms within a few minutes [161], and in most severe cases, muscle twitching, profound weakness, profuse sweating, incontinence, mental confusion, and progressive cardiac and respiratory failure may ensue [159, 161]. Seizures are relatively uncommon [162] as a primary complication in

severe carbamate poisoning because their penetration into the central nervous system is limited. Seizures may occur secondary to hypoxia, however. Death has occurred within a few hours in untreated cases and is usually due to respiratory failure [159, 163]; pulmonary edema and evidence of cerebral hypoxia are the main findings at autopsy [159, 161]. In patients who survive, coma may persist for 18–24 h [161].

In less substantial ingestions, cholinergic symptoms are evident within 2 h in most cases and typically resolve within 24 h [164]. There is some evidence that central nervous system depression in moderate carbamate poisoning is more common in infants than in adults, possibly as a result of a greater blood–brain barrier permeability [164]. Acute pancreatitis is reported rarely after ingestion [165, 166]. Klys and colleagues [167] reported a case of deliberate carbofuran ingestion in a young pregnant woman, which resulted in fatal carbamate poisoning in the fetus, although the mother survived. At autopsy, the fetal liver contained 2.5 µg/g of carbofuran, which was comparable to the maternal blood carbofuran concentration of 2.6 µg/g.

Although most carbamate insecticides are less toxic than OP insecticides, they should not be considered toxicologically benign. Severe cholinergic effects may ensue after ingestion, and unless supportive care, often with atropinization, is instituted promptly, significant morbidity may ensue. Deaths have been reported [162].

Delayed Neurological Sequelae

Carbamate poisoning is generally held not to be associated with delayed polyneuropathy such as is seen with some OP insecticides, but three cases have been reported involving ingestion of carbaryl [168], m-tolyl methylcarbamate [169], and carbofuran [170]. The first developed a sensory–motor neuropathy [168], while the second had loss of large myelinated fibers and axonal degeneration on sural nerve biopsy [169]. The third [170] developed arm and foot sensory symptoms and muscle weakness on the sixth day after hospitalization; the sensory component resolved rapidly, but motor features accompanied by abnormal electrophysiological studies persisted

for several months. Lotti and Moretto [171] concluded that high doses of carbamate may cause a sensorimotor polyneuropathy in humans similar to OP insecticide-induced delayed polyneuropathy. Moreover, carbamates may exacerbate polyneuropathy initiated by prior dosing with an OP insecticide or by underlying subclinical axonal damage.

Peripheral neuropathy was also seen in 3 out of 36 patients aged 14–70 years poisoned with carbamates, 80% of exposures involved carbofuran [172]. Though it is not clear whether this finding was carbamate induced or predated the poisoning, other common causes of neuropathy, especially ethanol, were carefully excluded leaving carbamates as the probable explanation [172].

Diagnosis

Measurement of cholinesterase activity is unlikely to be helpful clinically because of the rapid course of the intoxication. Most laboratories are not acquainted with the special procedure required to assay red blood cell cholinesterase activity in the presence of carbamates. Samples must be kept on ice or frozen at –20 °C during transportation to the laboratory before analysis. Spontaneous reversal of the inhibition is rapid and is accelerated by the time interval between sampling and analysis; the dilution of the sample; the addition of substrate, usually acetylcholine, at high concentration (which competes successfully for the enzymatic active site); and duration of assay time. Laboratory assay should take less than 3 min and employ minimal dilution and minimal amounts of substrate [173].

Treatment

All cases of carbamate poisoning should be dealt with as an emergency, and the patient should be admitted to hospital as quickly as possible. Gastric lavage has no routine role in management even after substantial ingestion of a carbamate insecticide as its value is unproven and its execution is potentially dangerous because hydrocarbons are

present in many formulations. The capacity of activated charcoal to adsorb most carbamates has not been shown. While on theoretical grounds, the use of activated charcoal might be considered; in a large study in Sri Lanka, involving OP and carbamate insecticide poisoning, no benefit from single- or multiple-dose charcoal was demonstrated [83]. Patients were randomized to receive no charcoal ($n = 1554$), one dose of charcoal 50 g ($n = 1545$), or six doses of charcoal 50 g at 4 h intervals ($n = 1533$); outcomes were available for 4629 patients. 2338 (51%) individuals had ingested pesticides (1310 had ingested OP and carbamate insecticides), whereas 1647 (36%) had ingested yellow oleander (*Thevetia peruviana*) seeds. Mortality did not differ between the groups: 109 (7.1%) of 1544 participants in the single-dose charcoal group died (adjusted odd ratio 1.05, 95% CI 0.79–1.40) and 97 (6.3%) of 1531 participants in the multiple-dose charcoal group died (adjusted odd ratio 0.93, CI 0.69–1.25), compared with 105 (6.8%) of 1554 in the no charcoal group. No differences were noted for patients who took particular poisons, were severely ill on admission, or who presented early. Level of evidence for charcoal use in decontamination is therefore grade IV.

Bronchorrhea requires removal of secretions by suction and prompt relief with intravenous atropine (see below). Supplemental oxygen should be given to maintain arterial PaO_2 greater than 8 kPa (>60 mm Hg). If these measures fail, the patient should be intubated and mechanical ventilation instituted. Heart rate, blood pressure, electrocardiogram, and arterial oxygen saturation or blood gas tensions should be monitored.

Atropine

Atropine antagonizes the effects of accumulated ACh at muscarinic receptors. Atropine sulfate 2 mg (0.02–0.1 mg/kg in a child) intravenously should be given as soon as possible in moderately and severely poisoned adults and may be lifesaving in those with rhinorrhea and bronchorrhea (Grade I recommendation). The atropine dose should be titrated to control rhinorrhea and

bronchorrhea, to raise the pulse rate above 80 bpm, and to restore systolic blood pressure to more than 80 mmHg. In severe cases, several hundred milligrams may be required, though in a study in Sri Lanka, the mean dose was 23.4 mg (standard deviation 22.0, range 1–75 mg) [87].

If the initial dose produces only a partial response, it should be doubled and doubled again if there is only a limited clinical response [87].

An open-label randomized clinical trial was conducted in Chittagong Medical College Hospital, Chittagong, Bangladesh, on 156 hospitalized individuals with OP insecticide poisoning from June to September 2006 [88]. Group A consisted of 81 patients who received conventional bolus-dose atropine (increasing doses of intravenous atropine from 2 to 5 mg depending on severity, as assessed by the treating clinician, and repeated every 10–15 min until signs of atropinization were clinically evident); Group B consisted of 75 patients who received rapidly incremental doses of atropine (a first dose of 1.8–3.0 mg depending on severity as assessed by the treating clinician followed by another 5 min later at double this dose if needed. This was repeated every 5 min until all clinical signs of atropinization were clearly evident) followed by an atropine infusion (10% of the atropine required to load the patient was given per hour [e.g., if atropine required for atropinization was 18 mg, 1.8 mg was infused each hour]). The mortality in Group A was 22.5% (18/80) and in Group B 8% (6/75) ($p < 0.05$). The mean duration of atropinization in Group A was 151.74 min compared to 23.90 min for Group B ($p < 0.001$). More patients in Group A experienced atropine toxicity than in Group B (28.4% vs. 12.0%, $p < 0.05$); intermediate syndrome was more common in Group A than in Group B (13.6% vs. 4%, $p < 0.05$), and respiratory support was required more often for patients in Group A than in Group B (24.7% vs. 8%, $p < 0.05$). In this study, rapid incremental dose atropinization followed by an atropine infusion reduced mortality and morbidity and shortened the length of hospital stay and recovery.

Oximes

Eckert et al. [174] demonstrated in in vitro studies that HI-6, and to a lesser extent obidoxime, could accelerate the rate of decarbamylation of human erythrocyte AChE inhibited by physostigmine or pyridostigmine. In some animal studies [175–179], pralidoxime increased the toxicity of carbaryl, while in others [180] it protected against poisoning. More importantly, some human carbamate poisonings [181–185] have benefitted from pralidoxime though there has been at least one death despite its use [186]. At present there is insufficient evidence to either recommend or prohibit the use of pralidoxime in severe poisoning with carbamate insecticides (Level III evidence). Pralidoxime seldom should need to be administered in less severe cases since carbamates have a shorter duration of action than OP compounds. However, if intoxication is life threatening and unresponsive to atropine and supportive measures, pralidoxime chloride 30 mg/kg body weight by intravenous injection over 5–10 min should be given. Cases of mixed OP and carbamate poisoning should be treated as for OP poisoning.

Indications for ICU Admission in Organophosphorus Insecticide Poisoning

All cases of ingestion or substantial dermal or inhalational exposure
All patients with symptoms or signs of cholinergic excess (see Table 1)

Criteria for ICU Discharge in Organophosphorus Insecticide Poisoning

Absence of symptoms or signs of cholinergic excess >12 h after ingestion or substantial dermal or inhalational exposure; normal erythrocyte or plasma cholinesterase activity after organophosphorus insecticide exposure
No recurrence of symptoms or signs of cholinergic excess 24 h after discontinuation of oxime therapy

Common Misconceptions About Organophosphorus Insecticide Poisoning

1. Oximes are of no benefit in organophosphorus insecticide poisoning.
2. Oximes are of no benefit if started >24 h after the onset of organophosphorus poisoning.

Key Points in Organophosphorus Insecticide Poisoning

1. Depending on the organophosphorus insecticide, features of cholinesterase inhibition may be delayed for 12 h, particularly after dermal exposure.
2. The rate of spontaneous reactivation of organophosphorus-inhibited acetylcholinesterase depends on the chemical structure of the insecticide.
3. Oximes are indicated particularly in the management of poisoning due to diethyl organophosphorus insecticides.
4. Oximes must be administered in sufficient dose to reactivate inhibited acetylcholinesterase and be continued for as long as atropine is required.

Key Point in Carbamate Insecticide Poisoning

1. Severe cholinesterase inhibition after carbamate insecticide exposure usually occurs only after ingestion and typically resolves within 24 h.

Bipyridyl (or bipyridinium) herbicides are quaternary ammonium compounds marketed as contact herbicides and desiccants in over 90 countries [1]. Paraquat is produced by a large number of companies across the world and is very widely used; however, it has been the subject of regulatory action and bans due to its degree of toxicity to humans. Diquat is much less widely used and often formulated in combination with paraquat or other herbicides. Bipyridyl herbicides that are little used or no longer marketed include cyperquat, diethamquat, difenzoquat, and morfamquat.

Bipyridyl herbicides are rapidly acting and nonselective, being toxic to a wide range of grasses and broad-leaved weeds when applied topically in the presence of sunlight. They exert their herbicidal activity by interfering with the electron transfer system, inhibiting the reduction of nicotinamide adenine dinucleotide phosphate to reduced nicotinamide adenine dinucleotide phosphate (NADPH) during photosynthesis [3]. In contrast to many other herbicides, they have no residual environmental activity because they are inactivated almost immediately on contact with most naturally occurring soils, forming an inert complex with clay minerals in the soil. This complex is harmless to both plant and animal life [4].

This chapter builds upon the chapter by Alan Talbot in the 1st edition and the paper on diquat by Jones & Vale, *Clinical Toxicology* 2000, 38, 123–128.

Chemistry

Paraquat (1,1'-dimethyl-4,4'-bipyridinium) and diquat (1,1'-ethylene-2,2'-bipyridinium) are bis-quaternary ammonium compounds, with molecular formulae of $C_{12}H_{14}N_2$ and $C_{12}H_{12}N_2$, respectively (Fig. 1). Both contain a bipyridyl ring structure and exist as divalent cations associated with anions such as bromide and chloride. Paraquat and diquat have molecular weights of 186.2 g/mol (cation) and 257.2 g/mol (dichloride) and of 184.2 g/mol (cation) and 344.0 g/mol (dibromide), respectively. Both are nonvolatile, freely soluble in water, sparingly soluble in lower alcohols, and insoluble in hydrocarbons. They are corrosive to metals and stable when stored in the original plastic container. They are strongly adsorbed to and inactivated rapidly by clay soils and anionic surfactants and can be decomposed by exposure to ultraviolet light [2].

Formulation

Paraquat is available for agricultural use as soluble liquid concentrate (SL), emulsifiable concentrate (EC), and soluble granule (SG) formulations. The SL and EC formulations typically contain 20–24% w/w paraquat ion, although novel generic formulations with higher concentrations have been developed. Granular formulations often

contain 5% or more paraquat ion with 50% formulations available.

The original SL product was an odorless red-brown liquid, which led to many cases of mistaken identification and unintentional fatal poisoning in the 1960s and 1970s [3, 4]. To reduce these poisonings, the formulation was changed in 1977 with the addition of a blue coloring agent, a stenching agent, and an emetic (phosphodiesterase inhibitor PP796). These additions are now part of the United Nations Food and Agriculture Organization's specifications for the herbicide. Unfortunately, there is little evidence that these measures improved outcome after ingestion, with vomiting being a common feature of fatal poisoning, although the coloring and stenching agents may have reduced the incidence of accidental poisoning [5].

There have been other more localized attempts to improve safety by changing formulations. The large number of fatal poisonings prompted Japanese authorities to replace the 24% SL paraquat product with a combined 5% paraquat/7% diquat SL product in 1986. Although this approach was intended to reduce the number of deaths [6], recent studies have shown no evidence that this change reduced fatality [7]. Instead, the number of deaths appears to have fallen in parallel with reduced importation [7]. A similar situation was observed in Samoa [8].

In 2004, Syngenta introduced a new Gramoxone INTEON formulation into Sri Lankan agricultural use. This product still contained 20% paraquat ion but also included an increased emetic concentration, a purgative, and an alginate that formed a gel under the acid conditions of the stomach, potentially slowing the absorption of paraquat and giving the emetic more time to be effective [9]. Unfortunately, the benefit after self-poisoning was modest with case fatality at 3 months falling from 73% to 63% in a large study of 586 patients (difference 9.5%; 95% confidence interval 2.0–17.1%; $p = 0.002$, log rank test) [10]. A further change in the INTEON formulation was introduced into Sri Lanka in 2006, with the active paraquat ingredient and surfactant sold in separate sachets. An ecological study reported the case fatality falling from 73% with the original formulation (297 patients from Dec 2003 to Sep 2004) to 65% with the first

Fig. 1 Chemical structures of paraquat dichloride and diquat dibromide

INTEON formulation (398 patients from Oct 2004 to Jan 2006; $p = 0.008$, Kaplan-Meier) to 55% with the second INTEON formulation (533 patients from Sep 2006 to Sep 2008, $p = 0.001$, Kaplan-Meier) [11].

Diquat is formulated as an aqueous SL concentrate, containing 20% diquat dibromide, or as an SG product, containing 2.5–5% diquat. However, it is often co-formulated with other herbicides, especially paraquat, in areas where the latter is permitted.

Both paraquat and diquat can be purchased for home garden use in some countries as 0.2% liquid formulations.

Incidence of Human Poisoning

Far fewer reports of human poisoning and death due to diquat poisoning have been reported than due to paraquat poisoning [12, 13]. Paraquat is modestly more toxic than diquat; their respective acute rat oral LD50 values are 150 mg/kg (paraquat) and 231 mg/kg (diquat). Both compounds are classified as WHO Class II “moderately hazardous” pesticides [14].

The epidemiology of paraquat poisoning has changed markedly over the last 50 years. However, precise numbers are not known, in part because of the lack of a specific International Classification of Diseases (ICD) code for bipyridyl poisoning, the lack of standardized data collection by poison control centers, and the lack of national databases in countries where the problem is large [5].

The first reports of fatal paraquat poisoning occurred in industrialized countries following accidental ingestion of concentrated products decanted into drinking containers [3, 15, 16]. These incidents became much less common in industrialized countries after enforcement of legislation to prevent decanting of herbicide and changes in formulation to stop confusion with soft drinks. Nearly all deaths in industrialized countries now occur from intentional ingestion [5, 17, 18].

The introduction of pesticides into rural developing world homes with the Green Revolution resulted in a massive increase in pesticide-related suicides as nonfatal self-harm with low toxicity poisons was converted into lethal poisoning with the highly hazardous pesticides recently

introduced into agricultural practice [19]. Paraquat has one of the highest case fatalities of any pesticide after ingestion, with deaths occurring in over 60% of patients presenting to hospital [20] and practically all patients ingesting more than 20 mL of the 20% formulation [10]. Although in some locations, such as the Caribbean and South Pacific [8, 21, 22], paraquat became the main cause of pesticide-induced suicide throughout the 1980s and 1990s, the highly hazardous WHO Class I toxicity organophosphorus (OP) insecticides were probably responsible for the great majority of pesticide suicides globally [23, 24].

The situation may now be changing with ongoing bans of highly hazardous OP insecticides in the developing world, where they cannot practically be used or stored safely, and the increased manufacture, export, and use of paraquat in China [25–27] and India [28]. An increasing number of paraquat poisoning deaths in China [27] resulted in 20% aqueous SL formulations being withdrawn in 2012 with a complete ban planned for 2016. A ban of paraquat in South Korea in 2011 has resulted in a 37% reduction in pesticide-related suicides [29].

Occupational exposure has resulted in death as well as less-severe injury from sustained dermal exposure, especially due to leaking backpack sprayers [30, 31]. Accidental poisonings after drinking water from discarded paraquat bottles still occur [32].

Most cases of diquat poisoning have resulted from the intentional ingestion of concentrated solutions [13, 33], although deaths have occurred after ingestion of 1.2% dilute products [34] and 5% granular products. Accidental ingestion has occurred as a consequence of decanting diquat concentrates into soft drink bottles [35]. There have been no large case series of diquat-poisoned patients with which to accurately estimate case fatality. However, it is likely to be similar to related paraquat formulations, given the similar mechanism of action, animal data, and human case studies.

Level of Evidence

Much of the evidence for diagnosis and management comes from case reports and case series

(Level 3). Prediction of outcome based on plasma paraquat concentration has been derived from large case series [36–38] and the different formulae tested in a large independent data set ($n = 451$) [39]. There have been several RCTs of immunosuppression to prevent paraquat-induced lung fibrosis [40–42] and large prospective studies of the effects of introducing a new formulation [10]. Assessment of literature reports requires information on the plasma paraquat concentration, which is unfortunately often lacking, particularly with cases encountered prior to the mid-1970s [43].

Pharmacokinetics

There are few data on the pharmacokinetics of paraquat and diquat in humans. However, a population analysis for paraquat was recently performed in a cohort of 78 Sri Lankan patients [44]. This showed a two-compartment toxicokinetic model with first-order absorption and elimination. The apparent clearance, volume of distribution, and elimination half-life of paraquat were calculated as 1.17 L/h, 2.4 L/kg, and 87 h, respectively. Creatinine clearance was the most significant covariate to explain between-patient variability in clearance [44].

In rats, both herbicides are absorbed poorly from the gastrointestinal tract; approximately 1–5% of an oral dose is absorbed systemically, with most being excreted in the feces [12, 13, 45]. Paraquat appears to be absorbed poorly from the stomach, but facilitated absorption takes place in the small intestine. A linear relationship was noted between the plasma concentration of paraquat and the paraquat content of the rat small intestine, but not the stomach [46].

Of note, in dogs, a greater proportion of paraquat – about 45–65% – is absorbed, consistent with the greater susceptibility of dogs to oral paraquat poisoning [47]. Slowing passage from the stomach to the small bowel slowed absorption, indicating the lack of absorption from the stomach. Only modestly greater amounts of diquat were absorbed in dogs (10–20%) [47] compared to rats (1–5%).

The absorbed fraction of an oral paraquat or diquat dose absorbed by humans is not known. Although initially proposed to be similar to the small amounts absorbed in rat [48], Davies argued that human paraquat absorption in humans is more likely to be similar to dogs, with around 40% of the dose absorbed by 6 h [49]. There is little information regarding diquat absorption; however, the blood concentrations of paraquat and diquat were similar after ingestion of a combined product, suggesting similar absorption [50, 51].

Liquid formulations enter the small intestine rapidly, particularly if the stomach is empty. The time at which the plasma paraquat concentration peaks is not known in humans, but is 60–75 min in dogs [47]. The few studies performed in humans suggest that peak plasma concentrations are attained well within 4 h [36, 52].

When absorbed, paraquat and diquat distribute to most organs. The highest concentrations are found initially in the kidney and liver, and, for paraquat, the lungs [51, 52]. Several organs, including the lung and skeletal muscle, provide reservoirs for paraquat, which then slowly redistributes into the bloodstream. Neither herbicide is bound by plasma proteins.

Large amounts of absorbed paraquat and diquat are eliminated in the first few hours after ingestion via glomerular filtration, with some contribution from renal secretion [53, 54]. Most of the absorbed dose is excreted unchanged in the urine within the first 24 h of ingestion, even in patients who develop renal failure. As renal function deteriorates, clearance decreases, resulting in a dramatic slowing in the rate of decline of plasma concentrations. The terminal plasma half-life of both bipyridyls can then increase from less than 12 h to 120 h or longer. In the Sri Lankan toxicokinetic study of patients with moderate-severe paraquat poisoning described above, the apparent elimination half-life was estimated as 87 h [44]. Paraquat has been detected in the urine up to 3 months after ingestion, possibly from a deep body compartment reservoir (see above) [52].

A study of eight patients poisoned by a combined paraquat (5%) and diquat (7%) product showed lower serum diquat concentrations after 24 h, despite similar concentrations at 24 h after ingestion, indicating more rapid elimination of

diquat [51] (or alternatively metabolism of diquat to monopyridone and dipyridone [13]). Absorbed paraquat and, at a higher concentration, diquat have been detected in the bile, suggesting the presence of an enterohepatic circulation that may be of greater relevance in the elimination of diquat considering its more rapid elimination [51, 55].

Pathophysiology

Bipyridyl herbicide toxicity is associated with NADPH depletion [56] and lipid peroxidation [57]. Flavoenzymes, such as NADPH-cytochrome P-450 reductase, xanthine oxidase, and mitochondrial NADH-quinone oxidoreductase, initiate the single electron reduction of paraquat or diquat to form the free paraquat/diquat radical (Fig. 2) [58, 59]. This radical is unstable, transferring an electron to molecular oxygen to form a superoxide anion radical, which causes the observed systemic toxicity [12]. The resulting superoxide anion radicals

react with one another, forming hydrogen peroxide and molecular oxygen, a reaction that may occur spontaneously or via the enzyme superoxide dismutase. Under normal circumstances, hydrogen peroxide is detoxified by catalase and glutathione peroxidase. However, when these protective mechanisms are overwhelmed, cellular toxicity ensues. Paraquat, and to a lesser extent, diquat toxicity is enhanced by the administration of oxygen in a rat model [60]. Animal studies indicate that the bipyridyl herbicides may also exhibit direct mitochondrial toxicity [61].

The lung is the primary target organ of paraquat toxicity in humans and several animal species because of selective uptake and accumulation of paraquat by type I and type II alveolar epithelial cells and Clara cells [62]. In contrast, animal studies indicate that diquat does not accumulate in the lung and has a half-life in the lung five times shorter than that of paraquat [63]. Paraquat uptake into the lung occurs by a slow, energy-dependent active transport process, reaching concentrations that may be 50 times greater than those in plasma

[64, 65]. Animal studies indicate that pulmonary uptake is virtually complete by 6 h [66]. Human studies suggest that there may be efflux of paraquat from the lung back into the circulation [67].

Paraquat uptake occurs via a transporter for endogenous polyamines, including putrescine [65, 68]. The transport process appears to require the structural feature of two positively charged quaternary nitrogen ions separated by a distance of 0.6–0.7 nm. Paraquat and the polyamines, but not diquat, share these features. This may be reflected in the relative lack of pulmonary uptake of diquat [69].

Paraquat produces degenerative lesions in the lungs accompanied by biochemical and ultrastructural changes of the pulmonary capillary endothelium and damage to the alveolar epithelium [62, 70]. In rat models, paraquat stimulates the infiltration of profibroblasts, which mature into basophilic fibroblasts. The coalescence of fibroblast clumps and the destruction of alveolar walls destroy the architecture of the lung parenchyma, resulting in diffuse intra-alveolar fibrosis [71, 72].

Clinical Presentation

Local Toxicity

Skin. The surface epithelium of the skin is normally an effective barrier to these herbicides. Diluted for spraying, they are unlikely to cause serious poisoning via the skin [73, 74], unless soaked clothing is worn for prolonged periods, the spray apparatus leaks, or protective clothing is not worn [31, 75–78].

However, concentrated formulations are strong irritants, causing dermal erythema, blistering, ulceration, and dermatitis [12, 13, 79]. Systemic absorption can then occur causing respiratory and renal failure and death [79–82]. Full thickness burns of the feet, requiring skin grafting, followed leakage of diquat from a backpack sprayer into the applicator's boots [83]. Nail damage occurs after contact with concentrated diquat or paraquat [84–86].

Inhalation. Aerosolized droplets have diameters exceeding 5 μm and therefore do not reach the alveolar membrane to cause either direct or systemic toxicity via inhalation. The vapor pressure of paraquat and diquat is low, making vapor inhalation unlikely and inhalational exposure rarely lethal [74]. However, excessive inhalation of the spray during formulation, mixing, or application can cause epistaxis, stomatitis, headache, and sore throat [87, 88].

Eyes. Severe ocular inflammation may develop if the eyes are exposed to concentrated solutions [89–92]. Inflammation develops gradually, reaching a maximum after 12–24 h, and may progress to ulceration of the conjunctiva and cornea. Healing is slow, although recovery is typically complete.

Mucosa. Corrosive damage to the oral mucosa, leading to burning in the mouth and painful hemorrhagic ulceration of the oropharynx and esophagus, is a common early feature following ingestion of concentrated paraquat and diquat solutions [93, 94]. Extensive local damage, as well as severe systemic effects, have followed intravaginal application of diquat and paraquat solutions [95, 96].

Systemic Toxicity

The severity of systemic toxicity is determined by the amount of diquat or paraquat absorbed. The vast majority of severe systemic poisonings and fatal cases have occurred after ingestion, although death has occurred after administration by parenteral injection [97, 98]. A dose-effect after ingestion is readily apparent (Fig. 3)

A grading system has been developed based on the amount of paraquat or diquat ingested (Box 1), separating toxicity into mild (grade 1), moderate-to-severe (grade 2), and acute fulminant poisoning (grade 3). Within 24 h of ingestion, patients with systemic poisoning develop lethargy, a widespread burning sensation, generalized weakness and myalgia, giddiness, headache, anorexia, and

Fig. 3 Effect of self-reported dose on outcome after paraquat poisoning.

Kaplan-Meier survival curves by ingestion amount in 297 patients who ingested the standard formulation of paraquat. A similar dose response was noted with the Inteon formulation (Taken with permission from Ref. [10])

fever. Fear and apprehension are prominent features, and restlessness is sometimes observed.

Box 1 Grading System for Toxicity Resulting from Ingestion of Bipyridyl Herbicides [13, 99, 100]	
Grade 1 Mild poisoning	After ingestion of <20 mg/kg paraquat ion or <50 mg/kg diquat ion In addition to gastrointestinal symptoms, acute kidney injury may occur together with, in paraquat poisoning, a transient decline in the gas transfer factor and vital capacity. Recovery is usual
Grade 2 Moderate-to-severe poisoning	After ingestion of 20–40 mg/kg paraquat ion or 50–200 mg/kg diquat ion Vomiting and diarrhea plus systemic features are seen. Multiple organ dysfunction is frequent, and acute renal failure in particular is common, but recovery may occur. Pulmonary fibrosis develops in all paraquat poisoning cases, but may resolve
Grade 3 Acute fulminant poisoning	After ingestion of >40 mg/kg paraquat ion or >200 mg/kg diquat ion Multiple organ failure develops and death occurs in most cases within 24–48 h

Gastrointestinal tract. Patients develop nausea, vomiting, abdominal pain, and diarrhea soon after ingestion as a result of local irritant action on the gut. In moderate-to-severe poisoning, a burning sensation, soreness, and pain in the mouth, throat, retrosternal area, and abdomen (usually epigastric, sometimes associated with guarding) are common [93, 99]. Severe and extensive inflammation and ulceration occur in the mouth, esophagus, stomach, and small intestine, with sloughing of the oropharyngeal mucosa, an inability to swallow saliva, dysphagia, and aphonia. Prominent pharyngeal membranes (“pseudodiphtheria”) occur [101]. Perforation of the esophagus may result in mediastinitis, surgical emphysema, and pneumothorax or pleural effusion in association with pleuritis [102, 103]. Ulceration usually heals in patients who survive.

Jaundice, hepatomegaly, and central abdominal pain due to pancreatitis are frequent complications [104]. At postmortem examination, centrilobular hepatic necrosis, bile duct injury, and cholestasis were observed [105, 106]. Raised serum transaminase and pancreatic enzyme activity is correlated with poor outcome [107, 108]; however, these rises can be mild and resolve spontaneously in less-severe poisoning [109].

Renal. Oliguric or nonoliguric renal failure may occur, usually due to acute tubular necrosis,

becoming evident after about 24 h [110–112]. Rarely, glomerular and tubular hemorrhage may be found [94]. In other cases, proximal tubular dysfunction may develop within 2–6 days and may progress to anuria. Hypovolemia, after sequestration of fluid in the gut, may also cause renal failure by reducing renal perfusion. Renal dysfunction commonly results in proteinuria, microscopic hematuria, glycosuria, aminoaciduria, phosphaturia, and excessive leaking of sodium and urate [111].

Pulmonary. Many patients develop a cough, which may be productive and blood-stained. Dyspnea is a prominent feature and occurs early in patients who have ingested substantial doses, particularly of paraquat, due to the development of adult respiratory distress syndrome and/or bronchopneumonia. Occasionally, pneumothorax (in association with mediastinitis), pleural effusion, and iatrogenic pulmonary edema may precipitate dyspnea [113]. In addition to a declining gas transfer factor and vital capacity, severely poisoned patients have a low and declining PO_2 with resultant central cyanosis. Radiologic changes do not always parallel the severity of clinical symptoms. The chest x-ray may be normal, particularly in patients dying early from multiple organ failure. Respiratory failure with need for mechanical ventilation may occur.

In patients less-severely poisoned by paraquat, the onset of dyspnea may occur later and be caused by pulmonary fibrosis. Patchy infiltration occurs on x-ray, which may progress to an opacification of one or both lung fields. Survivors of paraquat poisoning may recover normal pulmonary function or be left with a restrictive type of pulmonary dysfunction [114–116]. Such fibrosis has not been reported in diquat-poisoned patients.

Cardiovascular. Except for sinus tachycardia, cardiovascular complications are usually not observed until the terminal phase of poisoning. Ventricular tachycardia, intraventricular conduction disturbances, and nonspecific T-wave changes on electrocardiogram occur in the terminal phase. Sinus bradycardia, hypotension, and cardiac arrest may supervene. Chest x-ray may

show massive cardiomegaly, and at postmortem examination, toxic myocarditis and subendocardial hemorrhages have been found histologically [106].

Neurologic. Coma is a common terminal event in bipyridyl herbicide poisoning. Coma has been observed in association with brain stem infarction and pontine hemorrhage in diquat-poisoned patients [35, 117]. Convulsions and status epilepticus may occur in the terminal phase [118, 119] but are not common. Postmortem histology shows generalized brain oedema and hemorrhage [120]. A peripheral burning sensation has been reported to be a marker of poor prognosis and of higher plasma paraquat concentrations after paraquat poisoning [121].

Endocrine. At postmortem examination, adrenal cortical necrosis has been observed in patients who died with fulminant poisoning [122, 123]. Raised pancreatic enzymes are common in moderate-to-severe paraquat poisoning and are associated with poor outcome [108, 124].

Diagnosis

The diagnosis can usually be made based on the history, the local mucosal damage seen in the mouth after ingestion, and the ensuing characteristic organ damage. However, occult paraquat poisoning may present with only lung fibrosis [125].

The diagnosis of paraquat or diquat poisoning should be confirmed with laboratory analyses of urine or serum. A qualitative urine test should be performed with alkaline sodium dithionite (Box 2) [126–129]. The presence of paraquat turns the mixture blue while diquat turns it blue-green or yellow-green. It is important to ensure that negative and positive controls are analyzed with each patient specimen. There are no common false positives in these patients. Failure of the test is usually due to the use of sodium dithionite that has oxidized on storage [129]. The test has some prognostic value: in urine taken within 24 h of poisoning, concentrations less than 1 mg/L (no color to light blue) generally predict survival,

while those >1 mg/L (navy blue to dark blue) generally predict a poor outcome [38]. A negative test does not exclude the possibility of bipyridyl ingestion; repeated urine tests are suggested over the next 6 h. Plasma can also be tested for paraquat using sodium dithionite [130].

Quantitative methods of analysis in biologic fluids include spectrophotometry, ion-exchange chromatography, gas chromatography, and radioimmunoassay [129]. The serum paraquat concentration can be compared against a nomogram to predict outcome with good accuracy, especially for death (Fig. 4) [36, 37]. At serum paraquat concentrations expected in overdose (i.e., up to 10 mg/L), little interference occurs with laboratory tests. At higher serum paraquat concentrations, false elevations of creatinine and lactate dehydrogenase may occur when analyzed with the Jaffe reaction [131, 132].

At present, there are insufficient data to allow accurate determination of prognosis based on the admission plasma concentration following diquat poisoning [13]. A diquat-poisoning nomogram has not been developed.

Box 2

Ten mL of urine should be added to 1 mL of a 1% solution of 2 N sodium dithionite in 1 N sodium hydroxide. A blue color (λ maximum 603 nm) indicates paraquat while a blue-green color (λ maximum 603 nm) suggests diquat [126, 129]. The presence of both paraquat and diquat complicates measurement the concentration of either.

Prognosis

The quantity of paraquat in the specific herbicidal preparation and the volume ingested (one mouthful of a 20% solution is life-threatening) should be confirmed by examination of the container and contents if possible. There is a direct correlation

between the quantity of paraquat ingested and outcome (Fig. 3) [10]. In patients who claim to have had only dermal, inhalational, or ocular contact, it is important to determine whether ingestion has also occurred, as this affects exposure dose and, therefore, prognosis.

Bismuth and colleagues first identified several factors that predict severe toxicity. In particular, it was noted that the ingestion of concentrated solution on an empty stomach, the occurrence of esophageal and gastric mucosal lesions, and the development of renal failure were predictive of poor outcome [93]. There have since been multiple reports proposing markers of poor prognosis. Many of these have been based on plasma paraquat concentrations and therefore need time and a high-level analytical laboratory [41]. Others have proposed the use of relatively simple laboratory tests, such as serum creatinine or transaminase [74, 107, 133], pancreatic enzymes [108], arterial blood gases [134, 135], lactate [136–138], or critical care scores such as APACHE and MSAPS II [139, 140] to predict prognosis. Unfortunately, none of these systems have been systematically validated or compared in large prospective cohorts.

Measurement of plasma paraquat concentration correlates well with outcome within 24 h of exposure [36, 37, 38]. Prognosis can be determined from a nomogram which relates the initial plasma paraquat concentration and the time after ingestion to the probability of survival. Five different prediction methods had been published by 2009 [36–38, 135, 141], but none had been validated or compared with another in an independent prospective cohort. These methods were then compared using data from a prospective cohort of 451 Sri Lankan patients for whom admission plasma paraquat concentrations and outcome were obtained (Fig. 4) [39]. All methods showed comparable performance, with positive predictive values of 0.92–0.96 but lower negative predictive values between 0.59 and 0.73. All five published methods better predicted death than survival [39].

Concentrations of paraquat in urine obtained within the first 24 h of ingestion have also been used to determine prognosis [39]. Of 53 patients

Fig. 4 Paraquat nomograms and outcome.

(a) Paraquat concentrations and outcome of patients with paraquat poisoning using Jones, Proudfoot, Scherrmann, and Sawada prediction lines. All methods predicted that those patients with plasma paraquat concentrations above the lines were more likely to die than survive (*filled bullet* = fatality, *empty bullet* = survivor). (b) Paraquat concentrations and outcome from 277 patients with paraquat poisoning compared with the probability of survival estimated by Hart's nomogram (Taken with permission from Ref. [39])

with urinary concentrations of paraquat of less than 1 mg/L within the first 24 h, 15 survived. In patients who died within 24 h, the urinary paraquat concentrations were 10–10,000 mg/L, and in patients who died later from pulmonary fibrosis, the urinary paraquat concentrations were 1–1000 mg/L.

Treatment

Current treatment of paraquat or diquat intoxication is largely ineffective [43, 99, 104, 142]. In addition to providing supportive care, management involves attempting to remove the chemicals

from the gastrointestinal tract before absorption, increasing their excretion from the blood, and decreasing subsequent tissue damage (Fig. 2). Patients topically exposed to paraquat via the skin or eyes should have all sites of contact extensively irrigated with water.

Resuscitation and Supportive Care

With currently available treatments, the prognosis for critically ill paraquat-poisoned patients is extremely poor. Once the diagnosis is confirmed, management should focus on keeping patients comfortable and providing pain relief. Intensive care will not change the outcome; there is no indication for intubation in the acute situation, unless coma and respiratory failure might be due to a co-ingestion. However, due to the absence of pulmonary lesions, some critically ill diquat poisoned patients have been successfully managed with intensive care measures.

Hypoxemia should be treated conservatively due to animal studies suggesting that a high FiO_2 can exacerbate formation of oxygen-free radicals and thereby extend lung injury [60]. Standard practice is to reserve oxygen for patients with distressing hypoxia and dyspnea [104].

Patients are often dehydrated due to gastrointestinal fluid losses. This should be corrected with fluid resuscitation to maximize elimination before the development of tubular necrosis.

The severe pain of local ulceration is difficult to treat. Mouthwashes, ice-cold fluids and ice cream, local anesthetic sprays, and lozenges have been used with some success. Opiates, sometimes with benzodiazepines, are required in many patients to relieve general and local pain.

Gastric Lavage or Emesis

Early vomiting is common after significant bipyridyl ingestion [93, 142], meaning that the stomach is likely to be empty by the time a patient presents to hospital. Absorption of the herbicides from the small bowel is also rapid. This suggests that neither gastric lavage nor

forced emesis on presentation to hospital is likely to offer benefit.

There is no evidence that gastric lavage is clinically effective [99, 142]. Paraquat's corrosive effects risk esophageal perforation during passage of a lavage tube [143], especially if it is delayed more than 1–2 h. Large-bore lavage tubes are therefore contraindicated. There is no evidence that induced emesis after paraquat or diquat ingestion offers clinical benefit [142].

Oral Adsorbents

There is no clear evidence for clinical benefit from the use of oral adsorbents.

Investigation of a range of soils in the 1960s showed that montmorillonite bound strongly to paraquat and that bentonite (sodium montmorillonite) and Fuller's Earth (calcium montmorillonite) were particularly effective [144]. Single [145] or repeated [46] doses reduced mortality in rats even if given after a potentially lethal dose of paraquat.

Smith and colleagues recommended the use of these soils for treating patients [46]. Fuller's Earth is preferred, and still widely used, because it can be administered as a 15% (w/v) suspension, whereas bentonite swells in water and can be used only as a 7% solution. However, the use of these soils in poisoned patients has not met with the success of animal experiments. In two studies, Fuller's Earth was used for 72 patients [146, 147]; however, survivors had generally taken a nonlethal dose and neither publication reported any benefit. Although the initial 1971 study by Clark suggested that activated charcoal was ineffective [145], this has been disputed [148]. Activated charcoal is now also widely recommended for bipyridinium-poisoned patients.

A single dose of adsorbent should be administered to all patients at first presentation to medical care. (Grade III recommendation). It is possible that a small number of patients may benefit from a resulting modest decrease in absorbed dose.

Extracorporeal Removal

Hemoperfusion is used routinely in many East Asian centers for treatment of paraquat poisoning [149–151]. Paraquat clearance is similar for the kidney and hemoperfusion; the latter becomes comparatively more effective as renal function fails after several hours [152]. Hemoperfusion is more efficacious than hemodialysis [153]. However, no large-scale, high-quality RCTs have been performed to assess the effectiveness of hemoperfusion versus no extracorporeal removal. In all large series, hemoperfusion, with or without the addition of hemodialysis, did not improve the prognosis of paraquat poisoning when plasma concentrations were above the nomogram. There is a negative correlation between the amount of paraquat eliminated and the time of death: the larger the body burden of paraquat, the larger the amount of paraquat removed from the blood, and the greater the probability of early death [154].

Two studies have compared hemoperfusion alone with hemoperfusion followed by continuous veno-venous hemofiltration (CVVH) [155, 156]. Both found that the addition of hemofiltration increased the time until death (from 2.5 to 5 days, and from 5.1 to 8.6 days); however, the absolute mortality did not differ between groups since patients seemed to be shifted from the fulminant group to the still often fatal moderate-to-severe group (grade II evidence).

Gawarammana and Buckley [104] have argued that hemoperfusion or CVVH cannot reduce mortality since dog studies [157] indicate that it needs to be started within 2 h of ingestion to reduce uptake into the lung and prevent lung fibrosis (Fig. 5). In addition, paraquat renal clearance is excellent in the first 6 h post-ingestion, making it unlikely that a modest contribution from hemoperfusion will be clinically significant.

Diquat is cleared from the blood by hemoperfusion at similar rates to paraquat [153]. However, there remains a lack of evidence for effectiveness and a theoretical need to initiate treatment before distribution to tissues. The potential for cerebral hemorrhage dictates the cautious use of heparin during hemoperfusion.

Antidotes and Specific Treatments

Pharmacologic intervention in paraquat poisoning has not been successful [158]. Many agents reduce paraquat uptake into lung in vitro but fail to show protection in vivo [159, 160]. Antioxidants such as superoxide dismutase, selenium, salicylate, acetylcysteine, and vitamin C have been studied in animals and human cases without any clear evidence of benefit [104, 158, 161].

There is no antidote for diquat or paraquat poisoning [43]. Immunotherapy with paraquat specific antibodies or Fab fragments has been proposed and tested in animals. These tests showed that although the antibodies increased the concentration of paraquat in the plasma, they did not reduce tissue accumulation and were therefore unlikely to affect mortality [162, 163].

Prevention of Lung Fibrosis

The use of immunosuppressive therapy to prevent lung fibrosis was first proposed in 1971 [16]. Since then multiple immunosuppressive and anti-inflammatory drugs, such as azathioprine, beclomethasone, bleomycin, cyclophosphamide, and fluorouracil and fibrinolytics, such as potassium aminobenzoate, have been used with no clear evidence of benefit [158].

A regimen of intravenous cyclophosphamide followed by dexamethasone was advocated by Malone [16] then by Addo [143], although review of the data does not suggest clear benefit [41]. A Taiwanese group then combined intravenous cyclophosphamide with methylprednisolone, followed by oral dexamethasone. A small RCT reported benefit in moderate-to-severe paraquat poisoning (survival 43% [12/28] with standard care versus 72% [18/22; $p = 0.008$] with the immunosuppression) [40, 164]. However, the study was not analyzed on an intention-to-treat basis – such an intention-to-treat analysis did not show effectiveness [165]. Additional small trials have been performed; a Cochrane review of three studies including 164 patients reported that cyclophosphamide and corticosteroids might benefit patients [166]. A retrospective observational

Fig. 5 Modeling of hemodialysis efficacy by time post-ingestion. A model of the time-dependent effect of hemodialysis on plasma (black line), tissue (dashed line), and lung (red line) paraquat concentrations. It should be noted that there is minimal reduction in lung concentrations when instituted at 3 or 6 h post-ingestion (parameters from model developed by Pond et al. [157]) (Taken with permission from Ref. [104])

national study from Taiwan using insurance data has suggested that introduction of combined immunosuppression and hemoperfusion into clinical practice resulted in increased survival [167].

A Sri Lankan RCT directly compared intravenous cyclophosphamide and methylprednisolone, followed by oral dexamethasone, with placebo ($n = 299$ patients) and found no difference in mortality (Grade 1 evidence) [42]. Of interest, a post hoc analysis did suggest a small benefit during the 2-week course of dexamethasone that needs to be tested in a further RCT.

Treatment to inhibit fibroblastic proliferation such as lung irradiation [168–171] or drug therapy, with, for example, colchicine or collagen synthesis inhibitors, has been proposed without evidence of clinical benefit [172, 173]. Lung transplantation has been performed to treat fibrosis. However, the persistence of paraquat in the body often results in fatal redevelopment of paraquat toxicity in the transplanted lung; fatal complications of transplantation have also been reported [174–177].

Special Populations

Pediatric Patients

The clinical picture in paraquat-poisoned children [4, 15, 178–182] is similar to that in adults with early vomiting, corrosive effects on the oropharynx, and multi-organ failure or lung fibrosis, depending on dose. There are few reports of diquat poisoning in children [35, 183]. Children rarely provide a history of ingestion or are unable to identify of the liquid ingested (sometimes concentrated solution decanted into unmarked containers [4, 15, 184]), making diagnosis difficult [184]. The diagnosis may also be delayed because of a relatively symptom-free period that occurs after the initial vomiting. This delay can be avoided if a method for rapid detection of paraquat and diquat in gastric aspirate and urine is employed when the nature of the ingested fluid is not known [129].

Pregnant Patients

Maternal and fetal deaths have occurred after ingestion of concentrated paraquat [185–187]. Even emergent cesarean section did not save the fetus [187]. In two cases, the fetuses died while the mothers survived; one survivor later had a normal pregnancy, showing no evidence of teratogenicity from the earlier exposure [187]. There have been cases of survival of pregnant women after paraquat ingestion with delivery of a normal child at term [188–190]. In one case, the child developed acute lung injury from paraquat that remained present at 10 months of age [191]. Maternal, fetal, and cord blood paraquat concentrations in one fatal case showed that paraquat crossed the placenta and was concentrated in fetal blood to levels four to six times greater than in maternal blood [187]. Amniocentesis revealed amniotic fluid paraquat concentrations nearly twice that of maternal blood in a second case [187], while breast milk contained paraquat in a third case [192].

Elderly Patients

There is no published scientific experience specifically with paraquat poisoning in the elderly.

Pesticides and grain fumigants play an important part in the development of agriculture and enhance grain production in the world. Their use has led to improved quantity and better quality of crops, resulting in better availability of food grains to the population. Despite these benefits, the increased availability of pesticides and grain fumigants has led to them being misused as agents of self-harm [1, 2].

Pesticides are compounds used to control pests. Fumigants are pesticides mainly used to control rodents, insects, weed seeds, and fungi, typically where the grain is stored, as in silos or stores [3]. They are extensively used to protect grain during the transport in ships, containers, or railcars. Fumigants comprise a diverse group of compounds and exist in solid (aluminum phosphide), liquid (formaldehyde), and gaseous (ethylene oxide) forms [4]. Exposure to grain fumigants is generally accidental or suicidal. Being heavier than air, the gaseous forms tend to settle near the surface of the ground, resulting in potential exposure of unprotected workers walking in the store or silo. This chapter summarizes the potential adverse effects of phosphine and metal phosphides.

Phosphides (aluminum, zinc, calcium, and magnesium) are used worldwide as grain fumigants and rodenticides. These agents are highly efficacious in killing rodents and insects. They are inexpensive and simple to manufacture. Major advantages of metal phosphides are that they do not leave behind any toxic residue, and have no

of Medical Education and Research, Chandigarh, India
e-mail: bhalla.chd@gmail.com

adverse effect on the seed viability [4]. Phosphides are mixed with grains during storage in prefixed ratios. The moisture in the grain reacts with phosphides to release phosphine (PH_3) gas. Phosphine acts rapidly and kills the pests without leaving toxic traces on the grain. Any remaining residues are easily washed away with water before the grain is used for consumption.

History

The majority of deaths attributed to phosphides in the first 50 years of the twentieth century were due to accidental exposure to phosphine. Prior to 1980, aluminum phosphide (ALP) was not registered in India as a major self-harm agent. The first large series describing the human health hazards of toxic exposure to aluminum phosphide came from Northern India in 1985 [1, 5]. Following this, there was an explosion of reports from different areas of India, predominantly the northwest and central areas of the country [5–10]. Cases are now reported with increasing frequency from other parts of the world, especially Sri Lanka, Iran, Jordan, and Morocco [11–13]. Reports of poisonings from developed countries are uncommon and are mostly accidental [14, 15]. Recently, accidental exposure to phosphine gas has been reported from Middle Eastern countries due to inadvertent use of metal phosphides as pest control agents in the home [16]. There is also potential of these agents being used as chemical warfare agents or in terrorist attacks [17].

Physical Properties

Aluminum phosphide is available as greenish-gray tablet of 3 g which contains 56% aluminum phosphide and 44% ammonium carbonate. Some preparations such as Sanphos contain 5% ammonium carbonate and 40% inert ingredients. It is also formulated as pellets, granules, and as dust. Since late 1990s, ALP has been marketed in India mainly as granulated powder in plastic pouches [10 g] as Celphos. This has resulted in marked decrease in the mortality of ALP ingestion [1].

The toxicity of ALP is due to the release of phosphine (PH_3) when it comes in contact with moisture or gastric hydrochloric acid. Pure phosphine is a colorless and odorless gas. Authors have reported a “decaying fishlike” odor at phosphine concentrations of only two parts per million (ppm) [18, 19]. Zaebs et al. reported olfactory fatigue in workers habituated to working in an environment with phosphine concentrations as high as 50 ppm for several minutes [20]. Garlic-like odor is attributed to impurities such as substituted phosphines, diphosphines, and arsine.

Phosphine is flammable and spontaneous ignition of some tablet forms in air has been attributed to aluminum oxide and diphosphine gas [21–23]. There has been one published case report of spontaneous ignition of phosphine during gastric lavage [24]. However, cases of spontaneous ignition or illness in health-care workers due to secondary exposure to phosphine while managing patients in emergency departments of intensive care units has not been reported from other centers.

Zinc phosphide, widely used as rodenticide in Southeast Asia, is available as a dark gray powder or crystals with a rotting fishlike odor [4]. It is commonly mixed with wheat flour and made into small pellets for use as rodent bait. Calcium phosphide is available as a reddish-brown powder [25]. It is not readily available from commercial sources.

A standard 3 g tablet of ALP liberates approximately 1 g of phosphine gas. The remaining aluminum hydroxide residue is nontoxic [25, 26]. The release of phosphine from these tablets is even more vigorous when they come in contact with an aqueous acid, such as the hydrochloric acid present in the stomach [4].

Toxicokinetics

The majority of reported exposures between 1900 and 1960 were accidental, with inhalation being the most common exposure route [27]. The most common route of exposure today is ingestion when the phosphides are used as agents for self-harm. Some phosphine is liberated the moment

the phosphide contacts moisture in the oral cavity. However, the majority of phosphine is released upon reaching the acidic stomach juices [26, 28].

Granules or the powder form of aluminum phosphide is usually ingested in suicide attempts after dissolving in water or other liquid. This results in immediate release of phosphine to the atmosphere leaving very little in the liquid. This may be an important factor in the apparently decreased toxicity of powder and granular formulations [1].

Once released, phosphine is rapidly absorbed from the mucous membranes in the gastrointestinal tract. The highly soluble compound is widely distributed to all organs [25]. When inhaled, it is readily absorbed from the respiratory mucosa. Dermal and ocular absorption has also been reported, though to a much smaller extent [25]. After ingestion, phosphine is readily exhaled and can be detected on the breath. It can also be detected in the blood and liver [29, 30]. In an autopsy study, phosphine was detected in the lungs and gastrointestinal tract at autopsy [31].

If gastric lavage is performed on suicide victims, phosphine gas may escape and may not be detected in a lavage sample. One may be able to detect nontoxic aluminum hydroxide as a clue to the ingested agent, though aluminum hydroxide is also present in some antacid preparations. In urine, hypophosphite, phosphate, and phosphite may be detected as phosphine degradation products [32].

Pathophysiology and Toxicodynamics

Phosphine is a cellular toxin, not unlike cyanide. The exact mechanism by which phosphine acts is not clear. Nakakita et al. [33] found that oxygen uptake in isolated rat liver mitochondria was inhibited by the presence of phosphine. Phosphine also inhibited adenosine diphosphate uncoupler and ion-stimulated respiration, but the exact target site was not identified. In a later detailed study [34], phosphine was found to be strong inhibitor of mitochondrial respiration in both the active (state-3) and resting (state-4) states in mouse liver, housefly flight muscles, granary weevils,

and beef heart. It was found to inhibit uncoupled site and ion pumping state affecting pyruvate, malate, succinate, glycerophosphate, and ascorbate cytochrome substrates. The effect was maximal on liver mitochondria, but intermediate in beef heart. This inhibition could not be reversed, suggesting that it is due to a direct effect on electron transport, which is the electrochemical link between respiration and oxidative phosphorylation in mitochondria. The spectral and dichroism studies revealed an interaction with the heme moiety of cytochrome oxidase (cytochrome c), but it has not yet been determined whether it interacts with either cytochrome a, a₃, or both (Fig. 1). In a study [35] involving three species of stored beetles, insect catalase, and not the cytochrome c oxidase system, was found to be inhibited. In an experimental study where parameters of energy metabolism and oxidative stress were measured in rat brain and liver after administration of ALP at the LD₅₀ dose (i.e., 10 mg/kg body weight), it was found that cytochrome c oxidase activity in platelets was inhibited in a concentration-dependant manner. Adenosine triphosphate (ATP) synthesis was found to be decreased, with a corresponding marked decrease in ATP concentrations in both the liver and brain. The activity of succinic dehydrogenase and NADH dehydrogenase were markedly lower. Liver glycogen content was depleted and the activity of glycolytic enzymes was increased. The activity of glucose-6-phosphate dehydrogenase was decreased in both organs. The results suggest that inhibition of cytochrome oxidase disturbs electron transport, leading to impaired energy production [36, 37]. The noncompetitive inhibition of cytochrome c oxidase results in tissue hypoxia and metabolic acidosis [36, 38].

Phosphine causes generation of highly reactive free radicals by inhibiting catalases, inducing superoxide dismutase, and decreasing glutathione concentration. The result is widespread damage to cellular membranes due to lipid peroxidation and protein denaturation [39, 40]. This damage then interferes with protein synthesis and enzymatic function leading to organ failure [5].

Recent studies indicate that various organs are affected in different ways [41]. When inhaled,

Fig. 1 Inhibition of mitochondrial respiration by ALP (From [http://medcraveonline.com/JACCOA/images\(Figure/JACCOA-02-00068-g001.png](http://medcraveonline.com/JACCOA/images(Figure/JACCOA-02-00068-g001.png) under a Creative Commons licence)

phosphine causes direct alveolar damage resulting in acute respiratory distress syndrome (ARDS) [5, 32]. There is also evidence suggesting diffuse endothelial dysfunction leading to systemic capillary leak characterized by ascites, as well as pleural and pericardial effusion [42].

Toxic Dose

Significant toxicity can result from relatively small doses of phosphine gas. The US National Institute of Occupational Safety and Health recommended safe level of occupational exposure to phosphine gas at the workplace is less than 0.3 ppm for up to 10 h per day [43]. At a concentration of 50 ppm there is an immediate threat to life, and exposure to 600 ppm for 30 min could be lethal [44].

Death has been reported following ingestion of as little as 4 g of zinc phosphide or 500 mg of aluminum phosphide [45].

Clinical Presentation

The clinical features of toxic metal phosphide exposure depend on the route, the dose, and the interval between ingestion and presentation [5, 45]. In many countries such as India,

attempting to harm oneself is illegal, leading to concealment of information about dose, the nature of the ingestion, and the elapsed time since exposure. Since most suicidal victims are adolescent females, it is necessary to maintain a high index of suspicion with this demographic [1].

Inhalation of phosphine is a difficult clinical diagnosis, although the smell of rotten eggs or a garlic-like odor may be an important clue [15]. However, these findings are frequently either absent or missed in a busy emergency department. Patients commonly report cough and breathlessness secondary to airway irritation [26], gastrointestinal symptoms, chest tightness, dizziness, diplopia, weakness, paresthesias, and tremors [2, 26].

The clinical effects of metal phosphide ingestion are summarized in Table 1. Almost all patients develop nausea, vomiting, retrosternal burning, and epigastric discomfort, which are also the most common clinical manifestations after inhalation. In significant poisoning, gastrointestinal manifestations are severe, and refractory hypotension, tachypnea, and shock invariably develop within 30 min to 2 h [4–8, 10]. Signs of sympathetic excess, such as sweating and tachycardia, are commonly observed. Cardiac dysrhythmias are a hallmark of metal phosphide poisoning and are typically fatal. Several electrocardiographic abnormalities have been reported

Table 1 Clinical features of phosphide poisoning

Following ingestion
Gastrointestinal: nausea, vomiting, epigastric discomfort, retrosternal burning, diarrhea
Cardiovascular: hypotension, shock, arrhythmias
Respiratory: tachypnea, cyanosis, adult respiratory distress syndrome
Hepatic: tender hepatomegaly, jaundice, elevated transaminases
Renal: oliguria, acute renal failure
Central nervous system: altered sensorium, restlessness, coma
Metabolic: metabolic acidosis, hypomagnesemia, hypermagnesemia, hypokalemia
Following inhalation
Chest tightness, cough, shortness of breath, and pulmonary edema if severe exposure

Table 2 Electrocardiographic changes in phosphide poisoning

Arrhythmias: sinus tachycardia, bradycardia, supraventricular ectopics, ventricular ectopics, atrial fibrillation, ventricular fibrillation
Conduction defects: wide QRS complex, A-V conduction defects, bundle branch block, complete heart block
ST-T changes: ST depression, ST elevation, T-wave changes

(Table 2). Oliguria develops in approximately half of metal phosphide poisoning cases. Adult respiratory distress syndrome commonly develops in severely hypotensive patients.

Following poisoning by a phosphide, restlessness, anxiety, and dizziness are expected, but sensory symptoms (e.g., paresthesias, numbness) and ataxia are not commonly reported. The sensorium is initially normal in most patients, until hypoxia supervenes resulting in altered mentation and delirium [5–7]. Seizures and deep coma are usually secondary to severe hypoxia. Acute kidney injury is caused by severe hypotension and typically presents clinically with a prerenal picture [5].

If the patient survives the shock phase, signs of capillary leak including ascites, pleural effusion, and ARDS may develop [42]. Other complications include disseminated intravascular coagulation, intravascular hemolysis, gastrointestinal

bleeding, fulminant hepatic failure, congestive heart failure, and, rarely, pericarditis [7, 26].

The outcome of patients poisoned by phosphides correlates best with the number of vomiting episodes after ingestion and severity of the patient’s hypotension and acidosis [46]. Theoretically, removal of as much of the tablets/granules as possible may help in reducing the toxic after ingestion. However, there is no data to support or refute the improved outcomes after gastric lavage in patients with phosphide ingestion.

The majority of deaths occur within the first 12–24 h after ingestion and are usually due to refractory hypotension and dysrhythmias. Deaths occurring more than 24 h after exposure are likely related to ARDS, liver failure, renal failure, or other complications [46].

Prolonged hypotension and hypoxia result in diffuse cellular damage in various organs. Reported autopsy findings include diffuse congestion of the liver, spleen, kidneys, adrenal glands, gastrointestinal tract, and brain, which correlate with the severity of hypotension. No specific changes are observed on histopathologic examination beyond visceral congestion, patchy liver necrosis, and neuronal injury in the brain [46].

Diagnosis

The following features, either alone or in combination, are of assistance in the diagnosis of metal phosphide toxicity:

1. History of ingestion
2. Symptoms and signs compatible with aluminum phosphide ingestion
 - (a) Mainly emesis with vomitus smelling like decaying fish or garlic
 - (b) Severe hypotension or shock
 - (c) Metabolic acidosis
 - (d) Abnormalities in cardiac rate or rhythm

The triad of hypotension, severe metabolic acidosis, and a garlicky odor on the breath should put this diagnosis high on the differential. Although the patient may be mentally clear immediately after ingestion, delay in accessing a health-care

facility may result in altered mental status by the time of presentation. Thus, mental status alone cannot be relied upon as an important clue for clinical diagnosis.

The diagnosis of phosphide exposure can be confirmed through detection of phosphine in exhaled air or stomach aspirate using the silver nitrate test. In this test, diluted gastric contents are heated in a flask and a strip of filter paper impregnated with freshly prepared silver nitrate is held near the flask mouth. The presence of phosphine in the fume turns the filter paper black [47]. While this test can also be performed by having the patient exhale into the silver nitrate paper, the results are not reliable. A false-negative result may occur in patients receiving supplemental oxygen due to phosphine being converted to phosphorus pentoxide; a false-positive result may occur in the presence of hydrogen sulfide in the air [48, 49].

Neither phosphine nor its metabolites can be reliably detected in urine or blood [49]. While breath phosphine can be detected using phosphine detector tubes, gas chromatography with nitrogen–phosphorus detection (GC-NPD) is usually recommended [50, 51]. The gold standard for phosphine detection is GC-NPD, but performing this analysis is often cost prohibitive in developing countries [51].

For spot sampling of phosphine in air, detector tubes and bulbs can be used and are important tools for the investigation of air quality at the site of accident/incident.

In a suspected case of poisoning, initial investigations should also be aimed at detecting organ system dysfunction. Chest X-ray and electrocardiogram are done to rule out dysrhythmias, aspiration, and ARDS. Electrocardiographic abnormalities are varied and nonspecific. They range from tachycardia, nonspecific ST and T-wave changes, and conduction abnormalities [7, 52, 53]. Atrial flutter and fibrillation and ventricular tachycardia and fibrillation are commonly observed dysrhythmias [54].

Echocardiography may reveal hypo- or akinesia of the left ventricle (LV), LV dilatation, and systolic dysfunction [13, 55, 56].

Arterial blood gas analysis is important in order to diagnose hypoxia and metabolic acidosis.

The most common finding is metabolic acidosis with respiratory alkalosis [57]. Serum electrolytes, blood sugar, liver, and kidney function tests are done to get the baseline data at presentation so that remedial measures can be taken. These tests can be repeated to evaluate declining organ function.

Magnesium levels in aluminum phosphide poisoning are variable and do not help in guiding the clinical management [4, 5, 26, 27, 58–61]. Both hypo- and hyperglycemia have been reported, and these conditions should be managed in standard fashion [62–64].

Treatment

Early recognition and management of phosphide poisoning is essential. Young patients presenting with severe metabolic acidosis and hypotension having raised jugular venous pressure/high central venous pressure should be suspected of phosphide poisoning if coronary artery disease and sepsis can be ruled out and one is an area where phosphide poisoning is common. It is important to take a detailed history and find out the exact nature/formulation of the compound ingested. Preparations made with large-sized tablets may lodge in the esophagus. Phosphine is rapidly absorbed from the mucous membranes and has a significant cutaneous absorption. Rapid mucosal absorption can lead to significant systemic symptoms even in the absence of the tablet reaching the stomach. Decontamination can be simultaneously carried out while examining the patient in the emergency [46].

Removing clothes soiled with patient's vomitus and washing the skin with water is sufficient. Induction of emesis is contraindicated, though spontaneous vomiting often occurs.

Although gastric lavage is no longer routinely used for most poisonings, lavage with potassium permanganate (1:10,000), which is known to oxidize phosphine, may be beneficial if done within the first hour of ingestion and if available [65, 66]. However, there is no evidence that gastric lavage improves outcome in poisoned patients, and it can be associated with

complications including aspiration, hypoxia, and tachycardia in an agitated, obtunded patient. Alternatively, the potassium permanganate can be administered through a nasogastric tube (Grade III recommendation).

Sodium bicarbonate has been tried as a neutralizing agent for gastric acid, but there is no definitive evidence of its utility [4, 26, 65]. Moreover, many patients present late in the course of illness when phosphine has already been absorbed.

Intragastric administration of a slurry of activated charcoal (adult 50–100 g, infant 1 g/kg, child 1–12 years 25–50 g) has been advocated in the past; however, no studies are available in literature that shows that it benefits patients. Therefore activated charcoal cannot be recommended [65].

There is experimental evidence of inhibition of phosphine release when vegetable oil (e.g., coconut oil) or liquid paraffin has been used after ingestion of aluminum phosphide tablet [67]. This practice was shown to benefit a patient in a single case report [68]. Since administration of any kind of oil/paraffin may be associated with a risk of aspiration in an agitated/comatose patient, it cannot be recommended and has not been used routinely in centers across the world [4].

Since phosphine can be released from the nasogastric or urogastric tube, while gastric lavage is being performed, there is a concern regarding secondary exposure to health-care workers. It is advisable to use universal precautions while handling these cases even though there is no documented evidence of any significant illness/poisoning in health-care workers taking care of metal phosphide poisoned patients [69, 70]. Phosphine is known to be flammable, but there are only two cases of autoignition that have been reported [22, 23].

The management of phosphide poisoning is supportive as there is no specific antidote. Ventilation for respiratory distress syndrome, replacement of electrolyte abnormalities, and early recognition/management of hypoglycemia are important [57, 62, 63]. Severe metabolic acidosis results in tissue hypoxia and can lead to significant myocardial depression. Early and effective

management of metabolic acidosis can be accomplished with the administration of sodium bicarbonate infusion or hemodialysis [32]. Management of metabolic acidosis can be difficult as high central venous pressure may preclude the use of large amounts of sodium bicarbonate and severe hypotension/shock may make hemodialysis life-threatening in these patients.

The primary aim of the management of phosphide poisoning is early recognition and aggressive treatment of shock [4]. Intravenous fluids are indicated as leakage of fluids from the intravascular to the extravascular space occurs as a result of capillary dysfunction [29]. However, these patients generally have high central venous pressures. Administration of excessive amounts of fluids has not improved outcomes and should be avoided [29]. Intravenous fluids should thus be judiciously administered and only after measuring central venous pressure or inferior vena cava (IVC) diameter. Bedside echocardiography may help guide management. A rapidly contracting left ventricle with a collapsing inferior vena cava would indicate fluid deficit, whereas a poorly contractile left ventricle with a full/dilated IVC would indicate a significant myocardial dysfunction [71]. Judicious administration of norepinephrine and vasopressin may help maintain blood pressure and improve peripheral perfusion [4]. Administration of dopamine or dobutamine is not recommended for hypotension as it may induce cardiac dysrhythmias [32].

Magnesium sulfate has been used in an attempt to prevent dysrhythmias from phosphide poisoning [58, 59] (Grade III evidence). In addition, it also has antioxidant effects suspected to combat free radical mediated injury. Although an improvement in dysrhythmia was noted, mortality was not affected. Amiodarone has been tried, but it can lead to hypotension and should therefore be used carefully [72]. The use of digoxin in these patients is controversial and has been limited to experimental studies only [73, 74].

In severe cases compromised adrenal function has been reported, but administration of steroids does not result in improved mortality [75]. Corticosteroid administration is not therefore routinely recommended by the author.

N-Acetylcysteine (NAC) has shown to benefit in experimental animal studies of phosphide poisoning [76]. The benefit may, however, be attributed to the fact that NAC was administered before the animals were exposed to phosphine. Two human studies reported conflicting results. One has shown some beneficial effects on mortality but has not taken into consideration the severity of poisoning [77]. The other study has failed to show any benefit in patients with refractory hypotension [78]. Therefore, NAC cannot be recommended as standard of care till more data are available. Some studies have shown inhibition of acetylcholinesterase [79–81] by aluminum phosphide and phosphine poisoning, but there have not been any studies to confirm the usefulness of oximes.

Glucose, insulin, and potassium (GIK) infusion administered to produce hyperinsulinemic euglycemia has been shown to benefit poisoned patients by providing energy, restoring calcium influx, and increasing myocardial contractility in patients with aluminum phosphide poisoning [82]. Most of the data has come from one center and needs to be reproduced at other centers before this can be advocated as standard of care (Grade III evidence). Because the efficacy of GIK has not been ruled out, in a patient with refractory cardiovascular decompensation, an attempt at its use cannot be faulted.

Hemodialysis/hemoperfusion does not remove phosphine but can help in management of metabolic acidosis or a fluid overload state [32]. Performing hemodialysis in a patient with severe shock can be detrimental and should only be done carefully.

Hemodynamic support with an intra-aortic balloon pump [83] and extracorporeal membrane oxygenation (ECMO) has shown to improve mortality [84], but the reports are from a limited number of centers. These therapies have significant drawbacks, including high cost, poor availability, and lack of expertise hampering larger clinical trials.

In the case of an inhalational exposure to phosphine gas, removal from the source and administration of oxygen has been sufficient therapy in the majority of the cases [32, 57]. The remainder of treatment is guided by the clinical condition of the

patient. Hyperbaric oxygen has been found to be of some survival benefit in animal trials but its usefulness in humans has not been studied [85].

Esophageal ulceration and erosions leading to bleeding have been reported after ingestion of aluminum phosphide tablets [86, 87]. It has been postulated that the large pill may result in exothermic damage to the esophageal mucosa and if it gets stuck, it may cause pressure necrosis [87, 88]. Although pressure necrosis has been ascribed as a cause of bleeding and esophageal strictures, yet, there has been no documented case of a stuck pill needing endoscopic removal in the series of cases published to date [86–88].

After the acute phase is over, this may result in esophageal strictures in survivors of aluminum phosphide pill ingestion [87, 88]. This complication has not been reported since granule formulations were made available. Patients developing upper gastrointestinal bleeding following aluminum phosphide tablet ingestion should be followed up carefully with endoscopy to look for development of strictures [88].

Prognosis

A large number of parameters [89] and critical care scoring systems [90, 91] have been evaluated as predictors of mortality in aluminum phosphide poisoning. However, low arterial pH, low sodium bicarbonate levels, hypotension (SBP < 90 mmHg), and altered mental status have been observed by many authors as predictors of poor prognosis [91, 92].

Prevention

An important preventive measure lies in better regulated supply of ALP. When properly used, it is an excellent and safe fumigant as it leaves little residue on grain. Legislative and administrative measures have been suggested to restrict and modify its supply. Unfortunately, there has been a failure in their application, except for the ALP's largest producer, in changes in formulation to granules, which has helped in reducing human mortality [1].

Rodenticides are utilized worldwide. Specific types of rodenticide exposures critical care physicians commonly encounter vary regionally. In the USA, before 1976, anticoagulant rodenticides contained warfarin. However, rodents developed resistance to warfarin, leading to the manufacture of more potent, longer lasting superwarfarins, also known as second-generation anticoagulants or long-acting anticoagulant rodenticides (LAAR). In the USA, the most common rodenticides involved in human poisonings are anticoagulant agents, specifically superwarfarin products. Annual reports of the American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS) reported ten deaths involving LAAR from 2002 to 2013. Superwarfarins are commonly present in homes throughout the United States, and exposure to them occurs frequently in the pediatric population [1–3]. The amount ingested is usually limited, and coagulopathy from single pediatric ingestions is rare [1–4].

Availability of various rodenticides within each country influences the likelihood of exposure. In the USA, rodenticides with high potential toxicity are available mostly to professional licensed exterminators as restrictions on production and distribution have become more stringent. In 2008, the US Food and Drug Administration (FDA) took steps to limit availability of ten active ingredients in rodenticides: brodifacoum, bromadiolone, bromethalin, chlorophacinone, cholecalciferol, difenacoum, difethialone, diphacinone (and its sodium salt), warfarin (and its sodium salt), and zinc phosphide. In 2015, one of the major producers of rodenticides Reckitt Benckiser Inc in the USA stopped distribution of 12 of their d-CON mouse and rat poison products [5].

Other rodenticides of higher order toxicity are available, but their use has been restricted or prohibited in many countries, including the USA. For example, *N*-3-pyridylmethyl-*N*-p-nitrophenylurea (PNU, VacorTM) was on the US market only a few years (1975–1979) before distribution was voluntarily halted owing to many

successful suicides with this product. Survivors developed insulin-dependent diabetes. Other highly toxic compounds used by commercial applicators in sheep collars for predator control are sodium monofluoroacetate and its metabolically related fluoroacetamide which inhibit a specific step in the tricarboxylic acid (Krebs) cycle. Though restricted in the USA, these agents remain readily available in many Southeast Asian countries.

Aluminum phosphide remains a common choice for suicide in a number of countries, such as Iran and India [6, 7]. It is far less commonly used for this purpose in the USA, with four deaths involving this agent in the 2002–2013 AAPCC TESS. Occupationally, phosphine (formed from phosphide) exposures and toxicity occur during grain fumigation in transport and storage areas [8–11]. Aluminum phosphide is discussed in greater detail in the chapter on phosphides and phosphine.

Bromethalin, which became available for use in the USA in 1986, has been involved in multiple exposures given its availability. Three deaths were attributed to bromethalin in the USA from 2002 to 2013.

Most of the remaining rodenticides that are discussed in this chapter are primarily of historical interest, particularly in developed countries where they are not commonly still used. However, in some parts of the world substantial numbers of exposures may still occur. For example, barium carbonate no longer is widely available as a rodenticide. It was sold as a water-soluble white powder. Many epidemics occurred when this rat poison was mistaken for flour [12–16]. Historically, many commercially available products contained strychnine, which at one time accounted for 30 deaths per year in the USA [17]. Four deaths attributable to strychnine were reported in the 2002–2013 Annual Reports of the American Association of Poison Control Centers Toxic Exposure Surveillance System [18–29]. Most human exposures to strychnine resulted from its prescription as an analeptic, analgesic, aphrodisiac, appetite suppressant,

Image 1 Anticoagulants (Courtesy of Nguyen Trung MD Poison control center, Bach Mai Hospital, Hanoi, Vietnam)

cathartic, circulatory stimulant, emetic, and tonic. Tetramine, still available in Southeast Asia, is often involved in multiple human exposures and deaths from refractory seizures [29]. Vitamin D exposures have occurred but in general do not cause critical illness. Other rodenticides of significance to the critical care physician are discussed in other chapters (i.e., arsenic, phosphorus, and thallium).

Biochemistry

Anticoagulants

Anticoagulant rodenticides are often combined with cornmeal, oats, or grain to increase palatability (Image 1). They can be tasteless, odorless, or foul smelling pending upon the agent. Most exposures are oral; however, they have been reported through the dermal and inhalational routes [3]. Specifically, brodifacoum is lipid soluble, concentrated in the liver, is approximately 100 times more potent than warfarin, and long lasting with clinical effects that can range from days to months (Table 1) [3].

α -Naphthylthiourea ANTU

ANTU (molecular weight 202) (Fig. 1) is a colorless to white-gray powder or crystal substance. It is odorless and bitter tasting. It has been a component of a number of rodenticide products (see Table 2).

Barium

Barium rodenticides no longer are available for sale in many countries, including the United States, but old product may remain. Barium carbonate is a white powder usually prepared of one part barium carbonate and four parts of a protein carbonate rich food such as rolled oats or fish meal mixed with milk or water [30]. Barium carbonate as a powder may be inhaled and cause acute paralysis [31].

Bromethalin

Bromethalin is odorless and crystalline yellow or white in color. It is commonly packaged into green pellets of approximately 7.5% concentrate

Table 1 Available forms of long-acting anticoagulant rodenticides

Rodenticide	Concentrations (%)	Forms	Brand names
4-Hydroxycoumarins			
Brodifacoum	0.005	Bait	D-Con Mouse Prufe II
			Talon, Talon G, Havoc
Bromadiolone	0.005	Bait	Bromone, Super-Caid
			Ratimus, Maki
Difenacoum	0.005	Bait	Ratak
Coumatetralyl			Endox, Endrocid
			Endrocode, Racumin
			Racumin 57, Rodentin
Indanediones			
Chlorphacinone	0.005	Bait	Caid, Drat, Ramucide
	0.25	Solution	Liphadione, Ratomet
	2.5	Concentrate	Microzul, Rozol
			Topitox, Raviac
Diphacinone	0.005	Cake	Diphacin
	0.05, 0.1, 0.2	Bait	Promar
	2	Concentrate	Ramik
Pindone	0.025, 0.1, 0.2, 0.5	Powder	Pival, Pivacin
	0.5, 1.5, 2	Concentrate	Pivalyn, Tri-Ban

α -Naphthylthiourea (From [124])

Fig. 1 Chemical structure of ANTU

[32]. Its major metabolite is desmethyl bromethalin formed by *N*-demethylation in the rat [32]. It acts as an uncoupler of oxidative phosphorylation and interrupts nerve impulse conduction.

Phosphides

Phosphides usually are found as powders or pellets and may have a rotten-fish odor (Image 2). Zinc and aluminum phosphide are the most

commonly available products. Calcium and magnesium phosphides also are available. In the presence of water and gastric acid, the metal is released, and phosphine gas (PH₃) is produced. This gas may have a garlic odor. Examples of reactions generating phosphine from phosphides are as follows:

Image 2 Phosphides (Courtesy of Nguyen Trung MD Poison control center, Bach Mai Hospital, Hanoi, Vietnam)

Fig. 2 Chemical structure of PNU

N-3-pyridylmethyl-N-p-nitrophenylurea (PNU)

PNU (Fig. 2) was sold as a yellow-green powder or cornmeal. A peanut odor may be evident. Examples of brand names in the USA have included Vacor Rat Killer, DLP-787 2% Bait, and DLP-787 10% House Mouse Tracking Powder.

Sodium Monofluoroacetate and Fluoroacetamide

Sodium monofluoroacetate is a white, odorless and tasteless salt that is added to grain baits (Image 3). It is absorbable by the gastrointestinal and pulmonary routes but not dermal routes, unless the skin is broken [33]. This product is isolated from African and Australian plants [34, 35].

Strychnine

Strychnine is an extract from the seed of Asian and Australian trees, including *Strychnos nux-vomica*. It is a bitter-tasting, odorless white powder. Table 3 lists strychnine-containing rodenticides [17]. Most products contain 0.5% strychnine.

Tetramine (tetramethylene disulfotetramine, TETS, TEM)

Tetramine is a white powder (Image 4). Its production has been banned in the USA since 1980. The dose of tetramine which kills 50% of mammals (LD50) is 0.1–0.3 mg/kg and doses of 7.0–10.0 mg are considered lethal in humans. Tetramine is approximately 100 times more toxic to humans than potassium cyanide and might be a more powerful human convulsant than strychnine [36].

Pathophysiology

Anticoagulants

Warfarin and warfarin-like anticoagulants disrupt enzymes in the liver (Fig. 3). These rodenticides inhibit liver vitamin K reductases, which are

crucial to endogenous activation of hepatically synthesized clotting factors II, VII, IX, and X and proteins C, S, and Z. These coagulation proteins are activated by carboxylation of terminal glutamic acid groups. Vitamin K is oxidized to an epoxide during this reduction reaction. Vitamin K₁ 2,3-epoxide reductase converts the epoxide to its quinone form, whereas vitamin K₁ quinone reductase changes the quinone into the active quinol form of vitamin K₁. In human overdoses, this inhibition is evident by an increased ratio of the epoxide to the quinol form [37]. Bleeding from the coagulopathy may occur when factor concentrations decline to less than 25–30% of baseline levels. Factor VII has the shortest half-life (approximately 5 h). After three to four half-lives (or 15–24 h), prothrombin time elevations can be seen. Bleeding complications usually manifest days after ingestion. The period of clinically significant anticoagulation for warfarin rodenticides typically lasts less than 1 week, whereas that induced by the long-acting agent brodifacoum may be months to longer than a year [3, 38–41].

ANTU

The toxicity of ANTU results from its active metabolites. Lung reduced nicotinamide adenine dinucleotide phosphate-dependent cytochrome P-450 enzymes seem to generate these injurious metabolites [42]. The thiocarbonyl group ($>C = S$) is most likely the site where a reactive intermediate is generated that subsequently binds pulmonary macromolecules and produces pulmonary injury [42, 43]. Glutathione depletion seems to exacerbate the toxicity [43]. Pulmonary edema may result from the injury. Rats also may metabolize ANTU [42]. It is not known why the lung is more susceptible to this compound than the liver.

Barium

Life-threatening barium toxicity results from actions on the neuromuscular and cardiovascular systems [44, 45]. Barium, after stimulating muscle, produces a depolarizing neuromuscular blockade [44, 46]. Potassium is shifted

intracellularly along with blockage of cellular potassium channel efflux [44, 46]. Profound weakness and partial paralysis result.

Bromethalin

Bromethalin uncouples oxidative phosphorylation and interrupts nerve impulse conduction. Toxicity is primarily related to the central nervous system manifesting as muscle tremors, myoclonic jerks, ataxia, seizure, and coma [32].

Phosphine

The mechanisms of phosphine toxicity are not completely understood; however, it may block cytochrome *c* and *a* oxidases [46]. Free radical generation and lipid peroxidation also seem to have a role [47, 48, 49]. Pulmonary edema is common and may develop over days. The toxicity of phosphine is discussed in greater detail in ► Chap. 94, “Phosphate and Phosphine.”

PNU

PNU is related structurally to alloxan, streptozotocin, and 1-methyl-1-nitrosourea. These antineoplastic compounds damage pancreatic beta cells [50–52]. Because of structural similarities, these compounds may be substituted for nucleotides. A substitution for nicotinamide in the generation of nicotinamide adenine dinucleotide and possibly nicotinamide adenine dinucleotide phosphate is a proposed mechanism. Nicotinamide adenine dinucleotide depletion has been documented after streptozotocin administration [50]. Cofactors no longer can function as hydrogen carriers for enzymatic redox reactions, including oxidative phosphorylation. The pancreas is especially susceptible because β cells are destroyed. The nervous system also may be affected, and neuropathies and encephalopathy may develop [53–55].

Fig. 3 Graphic depiction of the actions of warfarin on the vitamin K cycle

Sodium Monofluoroacetate and Fluoroacetamide

Sodium monofluoroacetate blocks the tricarboxylic acid (Krebs) cycle [34]. Fluorocitrate, its metabolite, accumulates and inhibits aconitate hydratase (Fig. 4) [56]. This inhibition disrupts cellular respiration, depleting adenosine triphosphate energy stores. The absorption, conversion, and inhibition lead to a delay of hours before effects appear [57]. This delay may be longer for fluoroacetamide because it is converted to fluoroacetate.

Strychnine

Strychnine acts on the central nervous system as a competitive antagonist at glycine receptors.

Although structurally dissimilar from glycine, its charge and surface configuration seem to allow binding at the glycine receptor site [58]. Glycine is the predominant inhibitory neurotransmitter in the brainstem and spinal cord. It acts by increasing chloride conduction in postsynaptic cells, causing them to be hyperpolarized. Strychnine blocks the postsynaptic binding of glycine. Strychnine also seems to block the action of γ-aminobutyric acid (GABA) in spinal interneurons, although this inhibition is not as potent as that with glycine [59, 60]. The GABAergic system provides the major neuroinhibitory pathways in the central nervous system. Benzodiazepines that are used to treat strychnine poisoning bind glycine and GABA receptor sites and increase chloride conductance [61, 62]. Barbiturates also enhance chloride conductance and have been reported to be effective in the treatment of strychnine poisoning [8, 63, 64].

Fig. 4 Interference of monofluoroacetate with the Krebs cycle

Tetramine

Tetramine is a noncompetitive GABA antagonist that acts by direct blockade of the chloride ionophore complex, blocking chloride channels in a fashion similar to picrotoxin [20].

Clinical Presentation

Anticoagulants

Patients with superwarfarin poisoning, may present with serious hemorrhagic complications. Most fatalities have occurred after intracranial

hemorrhages. Subdural, subarachnoid, retroperitoneal, and intracerebral hemorrhages have also been reported [3, 65–67]. These patients typically have bleeding from other sites or organ systems. Pulmonary hemorrhage may require ventilatory support [40, 41, 68]. Vaginal bleeding also has caused a fatal outcome [69]. Compartment syndromes have been reported [40, 41, 68]. Gastrointestinal bleeding and epistaxis should be anticipated and may be life-threatening. Clinical effects are often delayed as the onset of symptoms may be days or weeks after exposure, with one case report having a patient present to a health care facility 9 days after his overdose and another with presentation 3 weeks post exposure [67, 68].

ANTU

ANTU poisoning may have the potential for serious pulmonary toxicity in humans manifesting as the acute respiratory distress syndrome. Infrequent reports of significant toxicity simply may reflect that ingestions have not been large enough to produce serious poisoning. Brewer and Haggerty [17] suggested an oral mean lethal dose of 4 g/kg in primates. Shortness of breath and rales were noted after a large ingestion of 80 g of a 30% bait pack [70].

Barium

Facial paresthesias may be the first symptoms of barium toxicity [12]. These paresthesias may spread to the extremities [12]. Gastrointestinal symptoms usually follow and may include salivation, nausea, vomiting, abdominal pain, and diarrhea [12, 13, 71]. Gastrointestinal hemorrhage has been reported [12, 13]. In association with progressive hypokalemia, profound weakness develops and may progress to paralysis. Presentation may include ptosis, monoplegia, hemiplegia, and quadriplegia [12]. Most importantly, respiratory paralysis and respiratory failure characterize severe poisoning [45, 72]. Hypokalemia is also associated with cardiac conduction disturbances and dysrhythmias [70]. Electrocardiogram changes typically include QRS prolongation and flattened T waves and U waves [13, 71]. Ventricular extrasystoles, hypertension, and tachycardia may follow [45].

Ventilatory support may be needed for the respiratory paralysis [45]. Arterial blood gases may show respiratory acidosis as respiratory failure progresses. Cardiac monitoring is required to identify and treat any dysrhythmias that result from the intracellular potassium shifts and severe hypokalemia.

Bromethalin

Onset of toxicity is often immediate and manifests in central nervous system as muscle tremor,

myoclonic jerks, muscle flexion, ataxia, seizure, and coma [32].

Phosphine

Signs and symptoms of phosphide toxicity often develop within 15–30 min, and death may occur in less than 6 h [73]. Potency is highest when fresh, previously unopened tablets are ingested [74]. Open packages allow atmospheric moisture to react with tablets and decrease their potency. Banjaj and Wasir [75] stated that ingestions of 500 mg are usually fatal. Phosphides are potent gastric irritants; profuse vomiting and abdominal pain are often the first symptoms [74]. Tachypnea, hyperpnea, dyspnea, cough, and chest tightness usually follow. Tachycardia, hypotension, and arrhythmias may develop [76–79]. Central nervous system toxicity may include coma and delirium [73, 76].

Phosphides react with water to form phosphine gas. Though illegal in most first world countries, they are still quite available in many parts of the world. Recent media reports have implicated phosphine in the deaths of tourists in Thailand and two small children in Edmonton, Alberta, whose parents imported aluminum phosphide tablets from Pakistan to kill bed bugs [80, 81]. There have been many deaths reported in India and Iran [6, 7]. Phosphine is discussed in greater detail in ► Chap. 94, “Phosphate and Phosphine.”

PNU

PNU toxicity may manifest within hours or be delayed for days [82]. Anyone with a history of PNU ingestion should be observed, even if there are no manifestations of toxicity. Patients who develop signs of major toxicity should be admitted to an intensive care unit. Hyperglycemia or diabetic ketoacidosis follows the insulin deficiency from beta cell destruction, although hypoglycemia may precede these symptoms [83]. The onset of diabetes mellitus has been detected 4 h to 7 days after exposure [82, 84]. Autonomic and peripheral neuropathies causing postural

hypotension, diminished gastrointestinal and bladder motility, and motor and sensory loss may develop. The onset is often acute, manifesting in the first few hours, although in some cases manifestations can be delayed for days [84, 85]. These neuropathies may be reversible or irreversible [83, 84]. An acute cerebral encephalopathy also may develop [83, 85]. Other signs and symptoms may include delirium, confusion, lethargy, coma, memory impairment, dyskinesias, tremor, seizures, myoclonus, abdominal pain, chest pain, palpitations, and hypothermia [83–85]. On autopsy, pancreatic beta cell destruction and neuropathic lesions of the sensory spinal roots have been documented [85].

Sodium Monofluoroacetate and Fluoroacetamide

Neurologic and cardiovascular toxicity from sodium monofluoroacetate and fluoroacetamide has caused many fatalities, and intensive care unit admission is warranted in an exposed patient manifesting any signs of toxicity. Epigastric pain and vomiting may be the first symptoms to develop [86]. Mental status changes may include confusion, irritability, agitation, and coma [33, 87, 88]. Neuromuscular irritability may include muscle twitching, muscle spasms, and seizures [87, 88]. Electrocardiogram monitoring shows nonspecific ST wave changes, prolonged QT_c intervals, ventricular ectopy and tachycardia, and rapid atrial fibrillation. Hypocalcemia and possibly hypokalemia are common manifestations that may contribute to the aforementioned life-threatening conditions [56, 87]. Patients who survive beyond 24 h may develop renal failure [87, 88].

Gastrointestinal effects precede the life-threatening effects on the heart (ventricular dysrhythmias) and the central nervous system (coma and seizures) [33, 87, 88]. One report suggested that subacute exposure may result in sudden death [35]. Parkin and associates described a rabbit who developed chronic toxicity with renal, hepatic, neurologic, and thyroid dysfunction. Symptoms can be prolonged [89].

Strychnine

Initially a patient's apprehension may produce hyperventilation and respiratory alkalosis. When spasms compromise effective gas exchange, hypercarbia and respiratory acidosis may be seen [90, 91]. Finally, the spasms can produce a severe metabolic lactic acidosis with or without a respiratory acidosis. Often the pH can become significantly less than 7.1. Severe acidosis can precipitate multiorgan dysfunction and failure. Bradycardia and hypotension may precede cardiac arrest [92]. Lactic acidosis and hypoxia also may result in central nervous system depression. By the gastrointestinal route, signs and symptoms typically occur within 15–30 min. Nasal insufflation or intravenous injection can occur when strychnine is used as a substitute for drugs of abuse. In these cases, effects can occur within 5 min [90, 93]. Stimulation of the patient should be kept to a minimum. Loss of motor neuron inhibition causes hyperexcitability in affected muscles. The stimulation produces muscle twitching or spasms of extensor muscle groups, and trismus or opisthotonos has been seen [90, 93–96]. A unique manifestation of strychnine poisoning is an awake and alert patient with convulsions. Such patients may manifest seizure-like activity based on spinal hyperexcitability with relative noninvolvement of the brain. Stimulation may precipitate these effects [90]. In between spasms or after recovery, patients often describe severe pain during these episodes [94]. Between these events, the patient may be awake and relaxed. Respiratory compromise may occur secondary to spasms of the diaphragm and chest wall musculature [90]. Other complications may include rhabdomyolysis, hyperthermia, lactic acidosis, and multiorgan failure [90, 91, 97]. Severe spasms in addition to rhabdomyolysis may cause compartment syndrome [90]. Because strychnine poisoned patients are heavily sedated during the course of treatment, frequent examinations are required to assess distal extremity temperature, capillary refill, and firmness of the compartments. If there is any question of developing compartment syndrome, compartment pressures should be measured. The patient must be well hydrated to

avoid acute myoglobinuric renal failure. Central venous pressure monitoring should be considered if urine output decreases after appropriate volume expansion. Close monitoring of electrolytes is required. Derangements of potassium, calcium, phosphate, and magnesium may occur [91, 92, 96]. Hepatic and renal function should be followed in severely poisoned patients.

Tetramine

The most common routes of exposure are by ingestion and inhalation. Tetramine poisoning manifests primarily as refractory seizure, coma and myocardial ischemia. Clinical effects may occur approximately 30 min after exposure and last up to 13 h [36].

Diagnosis

Anticoagulants

Confirming the diagnosis requires a detailed history and laboratory analyses. Many patients who present with bleeding complications do not provide the history of exposure to anticoagulant rodenticides. Minor bleeding often occurs before a life-threatening bleed. When taking the history, search for liver disease or a possible cause of vitamin K deficiency in addition to other bleeding disorders, such as hemophilia, von Willebrand's disease, or coagulation factor deficiencies. Hepatotoxic liver disease (e.g., from acetaminophen, hepatotoxic mushrooms, or chronic alcoholism) could present with a bleeding complication although distinguishing features will be present. The various hepatotoxins are discussed in their respective chapters in this book. A prolonged prothrombin time or international normalized ratio (INR) may be a laboratory clue to the diagnosis. Coagulation factor levels should be measured and usually confirm the clinician's suspicion. These tests should be obtained before any blood products are administered. To assess quickly for coagulation factor depletion, the patient's plasma can be mixed with known normal

plasma. A 50:50 mixing of the two should correct the prothrombin time or INR if the cause of prolongation is factor deficiency.

Patients with severe hemorrhage may develop factor depletion or disseminated intravascular coagulation. D-dimer, fibrin split products, and fibrinogen levels help assess these diagnoses. Transfusions may be required. Liver function tests should be measured to rule out toxin-induced or other hepatic diseases, as mentioned earlier. Measurement of brodifacoum and other superwarfarin levels clarifies the diagnosis. However, concentrations of these rodenticides are frequently under the limits of detection of reference laboratories. Often this degree of testing is required if confirmation is desired because anticoagulant self-poisoned patients deny the ingestion of these products. However, a negative test does not rule out the diagnosis. Pediatric cases with serious bleeding complications are rare [98]. Most of these pediatric case reports are suspected to be Munchausen syndrome by proxy. In these cases, laboratory confirmation should be attempted for medicolegal reasons.

ANTU

The diagnosis of ANTU poisoning mostly relies on the history. Care must be taken to identify the product properly when possible. This diagnosis also should be in the differential diagnosis of a patient with a history of rodenticide ingestion who presents with pulmonary edema. Laboratory studies are of little help in the acute management of these patients.

Barium

The diagnosis of barium intoxication is typically made by history. Paralysis coupled with hypokalemia should confirm the diagnosis. Although barium can be measured in many matrices, including blood, serum/plasma, tissue, hair, and urine, obtaining barium levels do not enhance patient management. Although serum levels have been shown to correlate with toxicity, the patients

have been and can be managed appropriately without them [72, 99, 100].

Bromethalin

The diagnosis of bromethalin exposure is primarily made by history of exposure and clinical presentation consistent with neuromuscular hyperactivity. Levels and specific laboratory values are of little help in the acute management of these patients.

Phosphine

The clinical history coupled with the patient's clinical course make the diagnosis of phosphide poisoning. A rotten-fish odor can be an important clinical sign. One must be careful because off-gassing of the emesis can expose health care workers to phosphine fumes [6]. Laboratory tests are of limited diagnostic utility.

PNU

The diagnosis of PNU toxicity should be considered in patients with a history of rodenticide exposure and a presentation of diabetic ketoacidosis, especially with concomitant signs of neuropathy. Laboratory tests have only a confirmatory role and are not important to the acute critical care management of the patient and testing would be especially challenging given lack of availability of this agent.

Sodium Monofluoroacetate and Fluoroacetamide

The correlation of a clinical history of exposure with the onset of the clinical picture (initial gastrointestinal symptoms followed by mental status changes and cardiac toxicity) within hours of exposure is important to obtain the diagnosis. Fluoroacetate concentrations can be measured in serum, tissues, vomitus, and baits, but these

usually are not readily available. Laboratory consultation may provide confirmatory testing. In addition, in the correct clinical setting, elevated citric acid serum levels may support the diagnosis [101].

Strychnine

The history of exposure and rapid onset of symptoms, especially awake convulsions, often in less than 30 min, is expected in strychnine poisoning. Strychnine blood concentrations can be obtained but are not clinically useful, only confirmatory.

Tetramine

Acute refractory seizures lasting an extended period of time should heighten concern regarding exposure to tetramine, especially in the setting of a rodenticide exposure. Laboratory identification, though not clinically useful in an acute exposure, may be accomplished by several methods: including gas chromatography (GC) with nitrogen-phosphorous detection, GC with flame photometric detection, and GC-mass spectrometry [36].

Treatment

Anticoagulants

Gastrointestinal decontamination is of limited, if any, value in the management of the critically ill anticoagulant-poisoned patient. These patients present well after absorption and subsequent hepatic enzyme inhibition has developed. In the rare case of a patient presenting very soon after ingestion, activated charcoal may be warranted. However, in one case, multiple doses of charcoal did not seem to alter the outcome [3, 100]. There is no evidence that the administration of activated charcoal affects the outcome in these patients [102].

Critical care management decisions are based first on the bleeding complications the patient may develop and the severity of the coagulation defect. Control of hemorrhage should respond rapidly to the administration of whole blood, fresh frozen plasma, or factor concentrates. These blood products contain coagulation factors that stop ongoing bleeding (Level of Evidence [LoE] III). Whole blood reverses severe anemias that may develop. Prothrombin complex concentrates containing factors II, VII, IX, X, C and S may also be used in patients who cannot tolerate large volumes of Fresh Frozen Plasma (FFP) or whole blood (LoE III).

Indications for ICU Admission in Rodenticide Poisoning

Agent	Indication
Long-acting anticoagulants	Life-threatening hemorrhage
ANTU	Pulmonary edema
Barium Bromethalin	Ventilatory management, severe hypokalemia Refractory seizure
Phosphides	Hypotension, cardiac arrhythmias, coma, status epilepticus
PNU	Autonomic neuropathy with hypotension, encephalopathy, ketoacidosis
Fluoroacetates, fluoroacetamide	Cardiac dysrhythmias, coma, status epilepticus
Strychnine Tetramine	Status epilepticus or severe muscle spasms with ventilatory support, cardiac dysrhythmias, severe acidosis Myocardial ischemia, status seizure

Vitamin K therapy administration allows for the conversion of the coagulation factors into their active carboxylated forms. Vitamin K₁ is the only effective form (LoE III). For example, Aquamephyton is the parenteral brand available in the United States. Care must be taken with its administration because of the risk for anaphylactoid or possibly anaphylactic reactions from polyoxyethylated castor oil in its formulation [103]. To avoid these reactions, the rate of intravenous administration should not exceed 1 mg/min (LoE III). The use of a dilute solution also is

recommended because this step also may prevent anaphylactoid reactions (LoE III). The American College of Chest Physicians published consensus guidelines for parenteral vitamin K therapy in coumadin toxicity based on the INR. For patients with critical bleeding, 10 mg is recommended. If bleeding is not evident, INR results and recommended vitamin K doses are 6–10 (0.5–1.0 mg), 10–20 (3–5 mg), and greater than 20 (10 mg) [104]. Some medical toxicologists believe that the subcutaneous route is safer than the intravenous route and that the efficacy may be similar (LoE III). In either case, the benefits from vitamin K therapy are delayed for the approximately 6 h it takes for the hepatic elevation of active coagulation factor levels. If indicated, oral vitamin K therapy also should be initiated as soon as possible. Although the relatively slower oral absorption delays vitamin K’s effect, this route can be used to maintain elevated factor levels. Oral vitamin K doses of 100 mg to several hundred milligrams have been used [105]. Vitamin K has a half-life of less than 3 h [106, 107]. Without continued vitamin K administration, the coagulopathy may recur within 1–2 days. If the coagulopathy does not recur within 2 days of discontinuing therapy, vitamin K no longer should be required. When the bleeding complications are controlled, these patients can be transferred out of the intensive care unit.

ANTU

Most ANTU-exposed patients require close observation. Gastrointestinal decontamination with activated charcoal may decrease ANTU absorption in massive ingestions. Standard management protocols for pulmonary edema should be used for patients who manifest toxicity. Experimentally, and based on human case reports, fructose-1,6-diphosphate has been shown to protect the lung from ANTU-induced injury [108]. Fructose-1,6-diphosphate is an inhibitor of oxygen free radical production by neutrophils. Additionally, the preadministration of phorone produces an elevation of glutathione levels that protects against ANTU toxicity in rat models

[109]. Given this, *N*-acetylcysteine warrants testing as an antidote.

Barium

Barium carbonate is less soluble than other barium salts and may have a slower onset to effect. Activated charcoal binding of barium has not been studied but is not expected to offer significant benefit [107]. Although unproven, the administration of 30–60 g of magnesium sulfate or sodium sulfate has been recommended based on the theory of converting some barium into the insoluble salt barium sulfate, which would pass through the gastrointestinal tract without absorption [110, 111]. If larger doses are used, frequent measurement of sodium and magnesium levels must be done, especially if renal insufficiency develops. Despite oral sulfates, there are cases in which patients' conditions continued to deteriorate [112]. Intravenous sulfates are not recommended because these may induce barium sulfate precipitates in the renal tubules and lead to renal failure [72].

Potassium replacement is crucial (LoE III). Resolution of hypokalemia reportedly has coincided with recovery from the paralysis [99, 113]. Some authors believe that lowering the barium concentration is more important, however [72, 100]. Intravenous routes, including central lines using rates greater than 30 mEq/h, have been effective in elevating potassium levels in many cases [44, 71]. If emesis is controlled, one could administer potassium orally, and in critically ill patients this could be done via a nasogastric or orogastric tube [113]. However, hemodialysis may be more effective treatment as it directly removes barium [71, 72, 99, 100]. The addition of a high concentration of potassium (e.g., 4 or 4.5 mEq/L) to the dialysis bath elevates the serum potassium concentration. One patient 3 h into dialysis recovered from paralysis and was extubated successfully [99]. Hemodialysis should be the first line therapy in patients who have persistent paralysis despite adequate potassium replacement therapy, especially in patients with renal insufficiency (LoE III). Hemofiltration also has been used with success [114].

Bromethalin

Symptomatic and supportive care is the mainstay of treatment for this agent. Neuromuscular findings are probably best treated with appropriate agents such as benzodiazepines for seizures (LoE III). There is no available antidote for this agent.

Phosphine

Gastrointestinal decontamination after exposure to phosphides has not been studied. Patients develop nausea and vomiting from the irritant effects and [56] health care workers should protect themselves from the emesis because it theoretically may off-gas phosphine [74]. Jayaraman reported a physician who became symptomatic when the stomach of a suicide victim was exposed [6]. Though activated charcoal may be recommended, it is not known how well activated charcoal binds phosphides and has not been shown to alter outcome in these patients. Historically, dilution with bicarbonate solution has been recommended, although this treatment is based on theory and unproven [115]. The bicarbonate is believed to decrease the gastric hydrochloric acid concentration, which enhances the conversion of phosphides to phosphine gas. Another unproven recommendation is the use of diluted potassium permanganate to remove and oxidize the phosphides [115]. Duenas and colleagues [79] described the use of trimetazidine for the treatment of cardiac toxicity. They suggested that trimetazidine (an antianginal medication) may help mitigate the oxidant stress caused by phosphine [47]. However, trimetazidine is not widely available. Aggressive supportive care is the only approach that can be recommended at this time. This may include the use of extracorporeal membrane oxygenation.

PNU

Gastrointestinal decontamination using activated charcoal, particularly if it can be administered

very early, may be useful. However, it has not been shown to alter outcome in these patients. Management decisions depend on serum glucose determination and hemodynamic monitoring. Hypotension should be treated with volume expansion. If there is no response, a trial of fludrocortisone is warranted (LoE III) [82].

Nicotinamide (vitamin B₃) is a specific antidote for PNU poisoning. Animal models document nicotinamide's early benefits in treating streptozotocin and *N*-nitrosomethylurea toxicity [50, 51, 116]. However, the parenteral formulation is no longer widely available. Historical recommendations were to give 500 mg as a loading dose followed by 100–200 mg every 4 h for 2 days, not to exceed 3 g/day (LoE III). Children were to receive 50% of this dose (LoE III). The subsequent recommended oral dose was 100 mg three to five times per day for 2 weeks (LoE III). In animal models, protection was provided only when the antidote was given before or within hours of exposure [51]. The reported experience with delayed therapy in humans is disappointing [84]. Nicotinic acid was less effective than nicotinamide in a rodent model [117]. Nicotinic acid may not be a safe alternative because its vasodilatory effects may complicate the further treatment of hypotension [85].

Sodium Monofluoroacetate and Fluoroacetamide

Treatment of toxicity from sodium monofluoroacetate and fluoroacetamide consists of the stabilization of any cardiovascular or neurologic effects. If it is able to be given within the first hour postingestion, the administration of activated charcoal may decrease absorption. Theoretical recommendations for lavage with sodium bicarbonate or magnesium sulfate are unproven and most likely would not be of benefit. There are no proven antidotes for the management of these poisonings. Glycerol monoacetate, 0.1–0.5 mL/kg/h, as a Krebs cycle substrate replacement, has prolonged survival in a primate model, but it also

may aggravate toxicity and seems to be effective only early in the course [34, 118]. Ethanol, metabolized to acetate, also has been studied, with inconclusive results. In a more recent mouse model, simultaneous sodium succinate and calcium gluconate, but not calcium gluconate alone, reduced mortality [119]. Therefore, the mainstay of treatment remains critical care life support.

Strychnine

Signs and symptoms of strychnine poisoning can be seen within minutes depending on the route of exposure. Universal precautions should be maintained. Strychnine is absorbed rapidly through the gastrointestinal tract and mucous membranes. Strychnine is cleared by hepatic elimination via cytochrome P-450 system-mediated metabolism [92, 120, 121]. Very little strychnine is excreted unchanged in the urine. Attempts to enhance urinary elimination are of no benefit. Half-lives of 10–16 h have been reported [92, 122, 123]. Recovery within 12–24 h is expected when patients present before complications have developed [63, 95].

Treatment interventions may precipitate seizures; if the diagnosis is known, the patient should be administered benzodiazepines immediately (LoE III). Diazepam or midazolam provides a rapid onset of action. Propofol also may work through GABA agonism and may be an alternative (LoE III). The stimulation of gastric lavage also is contraindicated in a nonparalyzed patient. If the patient is asymptomatic, activated charcoal may theoretically decrease absorption if given within the first hour after ingestion. However, activated charcoal administration has not been shown to alter the outcome in strychnine poisoning. Because of the possibility of strychnine convulsions, giving anything orally after strychnine exposure should be done with great caution. When a patient is intubated, activated charcoal may be given by nasogastric tube. It is doubtful that gastric lavage would provide benefit.

The patient’s airway and ventilation must be monitored continually because respiratory compromise can occur at any time. Blood gases can reflect many abnormalities at different times in the poisoning [90]. Intubation allows aggressive pharmacologic management of the neuromuscular hyperactivity. In most cases, paralysis with a nondepolarizing neuromuscular blocker, such as rocuronium, is recommended to facilitate intubation because the stimulation of endotracheal intubation may precipitate spasms, including trismus or convulsions (LoE III) [96]. In addition to tactile stimulation, auditory and visual stimuli may precipitate seizures. Therefore, the resuscitation and intensive care unit atmosphere should be quiet, dark, and minimally invasive. Convulsions should be treated with benzodiazepines (LoE III), barbiturates (LoE III), or potentially propofol (LoE III). Continuous neuromuscular paralysis is another option if the patient cannot tolerate high doses of the aforementioned agents (LoE III).

Tetramine

No antidote exists for tetramine exposure. Activated charcoal should not be utilized in these patients given risk for aspiration from seizure. Empirically, exposed patients who are altered or seizing should be managed as one would treat a patient in status epilepticus. Universal precautions should be maintained [29].

Criteria for ICU Discharge in Rodenticide Poisoning

Agent	Criteria
Anticoagulants	Control of hemorrhage and reduction of international normalized ratio
ANTU	Improved oxygenation, off ventilator
Barium	Resolution of paralysis, weaning parameters met
Bromethalin Phosphides	Normal mental status Hemodynamic stability, coma resolution
PNU	Hemodynamic stability, acidosis controlled

(continued)

Agent	Criteria
Fluoroacetates, fluoroacetamide	Cardiac rhythm stability, no respiratory compromise
Strychnine Tetramine	Resolution of spasms and seizures with control of acidosis, off ventilator Resolution of seizures and control of acidosis off of the ventilator

Special Populations

Pediatric Patients

Children who present with bleeding complications indicating a significant exposure to anticoagulants warrant the consideration of Munchausen syndrome by proxy. Children rarely, if ever, of their own volition ingest enough brodifacoum to become critically ill with life-threatening hemorrhage [1]. In one report, children who had access to less than one box of the product could be managed without gastric decontamination [1]. In addition, children are likely to experience toxic effects from accidental pesticides exposure at lower doses as the dose per weight exposure is often more significant.

Common Misconceptions About Rodenticide Poisoning

1. Rodenticides other than long-acting anticoagulants are no longer a major risk in many countries because they are heavily regulated. Unfortunately, extremely toxic rodenticides are still readily available in some parts of the world and many products are unknown (Image 5).
2. Potassium replacement alone reverses paralysis in barium poisoning.

Image 5 Unknown product, many are mixed and the ingredients unknown (Courtesy of Nguyen Trung MD Poison control center, Bach Mai Hospital, Hanoi, Vietnam)

Key Points in Rodenticide Poisoning

1. In most cases, avoid decontamination procedures for strychnine and late-presenting anticoagulant poisoning.
2. The rapid onset of action of most rodenticides makes decontamination procedures of little benefit.
3. Extracorporeal removal speeds recovery from barium poisoning.
4. Respiratory compromise can be multifactorial and may develop quickly or can be insidious for rodenticides.
5. Acidosis and cardiovascular instability are common after exposure to many rodenticides.
6. Many antidotes are not readily available or may be experimental; consult a medical toxicologist when available.
7. The diagnosis of these poisonings is often difficult due to poor histories. Aggressive supportive critical care is the most important to enhance survival.

This chapter reviews the clinical presentation, mechanisms of toxicity, and clinical management of carbon monoxide (CO) poisoning. Emphasis is placed on the mechanisms for toxic effects of CO because this provides a demonstration of the continuum of CO-mediated effects, highlights common pitfalls in clinical management, and underscores the challenges that exist in clinical investigations.

Clinical Importance

CO is one of many ubiquitous contaminants of the environment that requires prevention and control measures to ensure adequate protection of the public health. The incidence of CO-related mortality and morbidity is similar worldwide and may be responsible for more than half of all fatal poisonings [1–3]. When normalized to regional population densities, fatality rates are around 0.5–1 per 100,000 in Belgium, Denmark, France, South Korea, Switzerland, Taiwan, the United Kingdom, and the United States [2, 4–14].

CO poisoning has been estimated to cause 40,000 persons per year to seek medical attention at emergency departments in the United States [15, 16]. More than half of the 6000 deaths from fires in the United States each year may be due to CO poisoning [17]. Deaths from suicides by CO poisoning average about 2600 per year in the United States, whereas unintentional deaths seem to be decreasing [2]. Between 1979 and

This chapter is an update of the chapter by Stephen R. Thom that appeared in the first edition of this book.

e-mail: Christopher.Hoyte@ucdenver.edu

1988, the rate of unintentional deaths decreased from 1513 to 878 deaths per year [2], and in the 1990s, the rate of unintentional deaths decreased to 600 deaths annually [15, 16, 18]. The decline may be a result of increased public awareness with the use of CO detectors and alarms, stronger emission controls placed on vehicles, and improvements in safety of heating and cooking appliances.

Despite efforts in prevention and in public and medical education, CO poisoning remains frequent [19–21]. Often individuals with CO poisoning are unaware of their exposure because symptoms are nonspecific and mimic those of viral illnesses. This situation contributes to misdiagnosis of many cases by medical professionals [19, 22–28].

Biochemistry

The toxicity of CO is due to its propensity for forming stable complexes with transition metals. In contrast to oxygen (O₂), CO does not participate readily in reactions involving formal transfer of electrons. Its valence bond configuration is the same as that of chemically inert nitrogen, [:C≡O:] [29]. CO exhibits a small dipole moment, which is what gives CO the tendency to form highly stable linear metal-ligand complexes.

The affinity of CO for hemoglobin is more than 200-fold greater than that of O₂, and formation of carboxyhemoglobin (COHb) is a recognized effect of CO exposure [30]. Pulmonary CO uptake and the variables that influence the body store of CO and COHb level can be estimated reliably by

the Coburn-Forster-Kane equation (Fig. 1). The major issues of clinical relevance are that CO uptake depends on the partial pressure of CO and O₂ in the inspired gas, the ventilatory rate, and the duration of CO exposure [31].

In the lungs, CO binds more slowly to hemoglobin than O₂ does, but this is more than offset by the extremely slow rate of dissociation of CO from hemoglobin. The CO-hemoglobin interaction exhibits cooperativity. COHb cooperativity is driven by the association of CO with hemoglobin, whereas cooperativity for oxyhemoglobin is driven by the off-reaction of O₂ from the two α and β globin chains due to the stability of the deoxy (T state) structure. CO binds to oxyhemoglobin (R state) more rapidly than to the deoxy (T state) structure; this results in two adverse effects for O₂ delivery. First, CO displaces O₂ and is bound to hemoglobin, reducing the amount of O₂ carried to the tissues. Second, the presence of CO in the heme pocket prevents modifications of hemoglobin interchain orientation and bond formation that normally occur with O₂ dissociation, the R state-to-T state conversion. The presence of CO increases the O₂ affinity of the protein, causing a left shift of the oxyhemoglobin dissociation curve. The resulting COHb dissociation curve has virtually the same shape as the O₂ dissociation curve. Because of the increased affinity of CO compared with O₂, the fraction of total hemoglobin converted to COHb increases steeply with small increases in CO partial pressure. At a CO partial pressure of only 0.16 mmHg, 75% of the hemoglobin is combined with CO; this is why relatively small amounts (<0.1% of inspired air) of CO can inhibit the function of a large

$$\exp(-tA/V_bB) - A[\text{COHb}]_t - BV_{\text{CO}} - P_{\text{ICO}} / A[\text{COHb}]_0 - BV_{\text{CO}} - P_{\text{ICO}}$$

$$\text{where: } A = P_{\text{CO}_2}/M[\text{HbO}_2]$$

$$B = 1/DL_{\text{CO}} + P_1/V_A$$

Fig. 1 Coburn-Forster-Kane equation. *T* exposure duration, *V_b* blood volume in milliliters, *P_{CO}* average partial pressure of oxygen in lung capillaries, *M* equilibrium constant for reaction of carbon monoxide (CO) with oxyhemoglobin, [*HbO₂*] oxyhemoglobin as milliliters of oxygen per milliliters of blood, *DL_{CO}* diffusing capacity of the lungs for CO in milliliters per minute per mmHg, *P_L* barometric

pressure minus vapor pressure of water at body temperature, *V_A* alveolar ventilation rate per minute, [*COHb*]_{*t*} milliliters of CO per milliliters of blood at time *t* after exposure, *V_{CO}* rate of endogenous CO production, *P_{ICO}* partial pressure of CO in inhaled air, [*COHb*]₀ carboxyhemoglobin in milliliters of CO per milliliters of blood before exposure. Units for partial pressures of gases are mmHg

proportion of the hemoglobin in blood. When this happens, the hemoglobin concentration and O_2 partial pressure of blood may be normal, but the O_2 content of the blood is grossly reduced due to the reduced amount of oxyhemoglobin. This reduction has important clinical implications. Chromatographic measurement of oxyhemoglobin does not monitor oxygenation status adequately. Pulse oximetry commonly is used in emergency departments and intensive care units, but values do not correlate with COHb levels and overestimate arterial oxygenation [32].

The affinity of CO varies with different heme-containing proteins because amino acid residues on the protein chains modify the binding pocket at the heme porphyrin ring. In the β chain of hemoglobin A, the E7 histidine and E11 valine residues sterically interact with the heme-bound CO and push the ligand off the heme axis. This interaction has a significant effect on the heme-CO bond and on the CO combination rate. In mutant hemoglobin A chains or hemoglobin molecules from other animals that do not have these types of steric hindrances, the CO combination rates are much higher [33]. Studies with synthetic iron porphyrin proteins have shown that amino acids can impede ligand binding by presenting steric hindrances to CO [34]. Other, more subtle variations in the heme binding pocket, the so-called docking site, also influence binding kinetics. The dissociation rates for CO vary markedly among different heme proteins. These rates cannot be explained based on steric hindrance, but they appear more likely to be related to alterations in the polarity within the heme pocket [35]. The amino acid residues surrounding the heme in myoglobin modulate ligand binding affinity. The binding affinity of CO compared with O_2 is reduced approximately 50-fold compared with the affinity for the free heme moiety. The difference in myoglobin is thought to be due to the characteristic geometry within the docking site, which impedes CO more so than O_2 [36].

Although clinicians may believe the details of CO chemistry have little relevance to their practice, these may have a substantial impact on understanding of the pathophysiology of CO poisoning. Physiologic stresses of CO classically

are related to competition between CO and O_2 for hemoproteins; more recent attention has focused on interactions between CO and another small gaseous ligand, the free radical nitric oxide ($\bullet NO$) (Fig. 2). Under virtually all circumstances, the affinity of $\bullet NO$ for hemoproteins is vastly greater than that of either CO or O_2 . Despite this fact, there are situations in which CO disturbs the association between $\bullet NO$ and hemoproteins. CO increases the steady-state concentration of $\bullet NO$ in and around platelets and endothelial cells [37–39]. Electron paramagnetic resonance spectroscopy has provided direct evidence that exposure to CO increases the concentration of $\bullet NO$ in the lung and brain [40, 41]. CO does not increase activity of nitric oxide synthase (NOS) in platelets or endothelial cells, and CO does not increase NOS protein concentration in tissues of CO-exposed rats at a time when they exhibit elevated $\bullet NO$ levels [37–39, 41–43]. CO partially inhibits NOS activity in rats exposed to 3000 ppm who have COHb levels of approximately 45% [37]. It seems that CO increases the steady-state level of unbound $\bullet NO$ because it competes for intracellular sites that normally would bind $\bullet NO$. Toxic effects on cells occur because the liberated $\bullet NO$ is available to undergo reactions with superoxide anion ($O_2^{\bullet -}$), which yield the potent oxidizing and nitrating agent peroxynitrite. These events are a component to CO-mediated brain injury in some animal models [40, 44–46], and they may relate to a growing body of evidence suggesting that CO functions as a cell-signaling messenger analogous to $\bullet NO$ [47, 48]. Whenever CO is generated in vivo by heme oxygenase, if $\bullet NO$ also is produced in the vicinity, the CO may act to increase the effective steady-state concentration of $\bullet NO$.

The mechanism behind the apparent ability of CO to increase steady-state concentration of $\bullet NO$ is under investigation. The following discussion relates my current hypothesis. It is based on an assessment of potential competition between ligands using published values for the association and dissociation constants for myoglobin, which may be used as a “model” intracellular hemoprotein (Table 1) [49].

Fig. 2 Interactions between carbon monoxide and the free radical nitric oxide ($\bullet\text{NO}$). *AA* amino acid, *MAO* monoamine oxidase, *NE* norepinephrine, *NMDA* N-methyl-D-aspartate

Table 1 Rate constants for different ligands with myoglobin

Gas	Association rate constant (M ⁻¹ s ⁻¹)	Dissociation rate constant (s ⁻¹)
O ₂	14 × 10 ⁶	12
•NO	17 × 10 ⁶	1.2 × 10 ⁻⁵
CO	0.5 × 10 ⁶	1.9 × 10 ⁻²

The calculated affinity binding constant favors $\bullet\text{NO}$ over CO by a factor of 10^5 when steady-state concentrations of CO and $\bullet\text{NO}$ are equal (e.g., for $\bullet\text{NO}$, $1.7 \times 10^7 / 1.2 \times 10^{-5} = 1.4 \times 10^{12}$; for CO, $0.5 \times 10^6 / 1.9 \times 10^{-2} = 2.6 \times 10^7$). It is unlikely, however, for both ligands to have equal concentrations in vivo. Coburn [50] showed that a predictable relationship exists between the tissue concentration of CO and blood COHb to a level of 50%. At a COHb of 7%, the extravascular fluid CO concentration should be approximately 22×10^{-9} M [50, 51]. Because CO is freely soluble, a similar concentration is expected to occur inside

cells. The rate of $\bullet\text{NO}$ production by endothelial cells (which may be taken as an example because these cells are physically close to delivered CO from the blood) has been estimated to be 1.1×10^{-18} M/cell/min [52]. Even in a situation in which there is a relatively low COHb, the CO concentration may be 10^9 greater than the concentration of $\bullet\text{NO}$. Competition is feasible even when considering equilibrium kinetics.

The potential for effective competition is even more favorable for CO when considering simple competition kinetics. It is more appropriate to make an assessment of competition using the association rate constants for these ligands, rather than the affinity constants. The physiologic and clinical settings where this relationship may have bearing are early during a CO exposure from exogenous sources, whenever there is a change in CO production in vivo, or when a reduction in local $\bullet\text{NO}$ production occurs. Because the association constant for CO and $\bullet\text{NO}$ differs by a factor of only 34, even a

small increase in CO concentration relative to that of •NO would have an impact favoring CO competition with •NO for myoglobin. Adverse effects on endothelial cells in vitro that are mediated by •NO-derived oxidants can be shown with exposure to a CO concentration of only 11×10^{-9} M [43]. There also may be physiologic conditions that allow favorable competition between CO and •NO. Liver parenchyma has been estimated to generate 0.45×10^{-9} M CO/g liver/min [53].

Pathophysiology

Hypoxic effects of CO were described by Bernard [54] and Haldane [55]. An elevated COHb can precipitate tissue hypoxia which seems to be responsible for fatalities, cardiac injuries, and the acute neurologic abnormalities that develop in approximately 14% of survivors of serious CO poisoning [56–58]. Clinical and animal studies have failed to establish a consistent correlation, however, between elevated COHb levels and delayed neurologic injuries. Delayed neurologic injury is the most frequent form of CO-associated morbidity [4, 59–66]. Studies indicate that 23–47% of patients with CO poisoning develop impairments of concentration and learning, dementia, cogwheel rigidity, amnesia, or depression 6 days to 3 weeks after poisoning [65, 67–69]. These events occur despite rapid and appropriate emergency care followed by careful neuropsychologic evaluations. CO poisonings that seem to be mild also may cause subtle neurologic dysfunction, which indicates that the clinical assessment of the severity of poisoning is unreliable [65, 70–72].

Severe CO poisoning causes mitochondrial dysfunction and oxidative stress in the central nervous system. In experimental CO poisoning, mild manifestations occur when cerebral perfusion is maintained, whereas mortality and morbidity are profoundly enhanced when exposures to high CO concentrations occur in the presence of reduced cerebral perfusion [73]. The concomitant impairment of cerebral blood flow can be triggered by cardiac

dysfunction due to CO or to fixed cerebrovascular lesions [73–77].

In the presence of concomitant hypoperfusion, Coburn and associates [78] showed that 20–45% of CO present in circulating blood shifts into skeletal muscle and other tissues. CO impairs mitochondrial electron transport when cells sustain a reduction in O₂ delivery, as occurs when an elevated COHb level occurs concurrent with restricted perfusion [75, 76]. In the setting of hypoperfusion and high CO concentrations, CO binds to cytochrome *c* oxidase, which inhibits adenosine triphosphate synthesis and causes generation of hydroxyl-like radicals [76, 79]. Energy production and mitochondrial function are restored as COHb levels decrease [76]. These observations have not explained the two historical characteristics of clinical poisoning that are correlated with a high risk for delayed morbidity: (1) a prolonged exposure to CO, called a *soaking*, and (2) syncope or temporary unconsciousness [59, 80–84]. It is unclear whether the transient changes observed during CO poisoning precipitate delayed neuronal dysfunction or death [85]. In some models with neuronal injuries, it has been difficult to document evidence of impaired mitochondrial function or a cellular hypoxic stress [77].

The level of CO in tissues likely has an equal or greater impact on the clinical status of patients and development of pathology than does the blood level of CO. This phenomenon is shown most clearly with regard to CO-mediated vascular injuries. When humans or experimental animals have been exposed to relatively low CO concentrations for extended periods, capillary leakage of macromolecules from the lung and systemic vasculature has been documented [41, 42, 86–89]. In contrast, when an hypoxic stress was established in animals by exposing them for 8–45 min to extremely high CO concentrations, sufficient to cause COHb levels of 60–90%, capillary leakage was not detected [90–92]. As noted in the prior section, a proposed pathologic mechanism of CO that is independent of hypoxic stress has been shown in experimental studies to be due to elevations in the steady-state concentration of the free radical •NO (see Fig. 2) [41, 42].

CO increases the steady-state concentration of •NO in and around platelets and endothelial cells [37–39]. Electron paramagnetic resonance spectroscopy has provided direct evidence that exposure to CO increases the concentration of •NO in the lung and brain [40, 41]. Some liberated •NO undergoes reaction with superoxide anion ($O_2^{\cdot -}$) to yield the potent oxidizing and nitrating agent peroxynitrite. The major product when peroxynitrite reacts with proteins is nitrotyrosine, which can be measured in tissues. Nitrotyrosine concentration is increased in the aorta, lung, and brain when rats are exposed to CO for more than 40 min, and it is found closely associated with the vascular endothelium [40–42]. CO causes a capillary leak in skeletal muscle and in lungs that is mediated by •NO [41, 42].

These findings have provided further insight into CO-induced neuropathology because endothelial •NO-mediated changes are a prerequisite for neutrophil adherence to the cerebral microvasculature of CO-poisoned animals [40, 45, 46]. •NO-mediated vascular stress is not sufficient by itself, however, to cause neutrophil sequestration in this model of CO-mediated brain injury. During the latter portion of the exposure, when rats breathe 3000 ppm of CO and become unconscious, they invariably sustain a period of hypotension that presumably is mediated by cardiac decompensation [44, 77, 93]. Cerebral blood flow, which initially is approximately 150% greater than normal due to •NO-mediated vasodilation, decreases to about 50% below normal for 4–6 min when rats lose consciousness [77, 93]. With regard to mechanisms of brain injury, in contrast to typical hypoxic-ischemic injury, there is never a time when cerebral blood flow is nil, and the interval of hypoperfusion is less than 6 min [77, 93]. The sudden reduction in microvascular blood flow, coupled with the •NO-mediated oxidative changes to endothelium, causes neutrophils to adhere to endothelium.

Activated neutrophils attach to the vascular wall via interactions between β_2 integrin adhesion molecules and endothelial counterreceptors [94]. β_2 integrin adhesion molecules are required for neutrophil adherence and progression of the oxidative stress cascade in CO poisoning [40, 46,

95, 96]. This cascade occurs 45 min after rats are removed from CO, based on the inhibitory potential of monoclonal antibodies to β_2 integrins [47, 96]. The 45-min delay between initial adherence and β_2 integrin commitment is unusually long compared with some models of leukocyte-mediated tissue injury. The delay is due to the flux of •NO from platelets [37]. Nitric oxide inhibits β_2 integrin function [97]. Activated leukocytes liberate proteases and reactive O_2 species that cause conversion of endothelial xanthine dehydrogenase to xanthine oxidase, and xanthine oxidase activity is required for subsequent brain lipid peroxidation [40, 44–46]. These biochemical events occur within 90 min after CO poisoning. Metabolic defects in the basal ganglia and hippocampus appear at 5 days, and evidence of impaired learning plateaus 3 weeks after poisoning [98]. The cellular and biochemical events that occur during this 3-week period are under active investigation [99]. In other models of CO-mediated brain injury, hyperbaric oxygen (HBO_2) therapy has been shown to diminish cerebral edema, reduce mortality, and improve neurologic outcome [74, 100, 101].

Several investigations have suggested an association between CO-induced neurotoxicity and neurotoxicity caused by excitatory amino acids [102, 103]. Although this issue currently is under investigation, at least in some studies excitotoxicity is linked to elevations of intracellular calcium, •NO, and $O_2^{\cdot -}$ [104, 105]. Three types of receptors are activated by excitatory amino acids: *N*-methyl-D-aspartate (NMDA), D-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, and kainic acid [104]. Agents that inhibit NMDA receptor activation attenuate CO-mediated delayed neuronal degeneration of pyramidal cells in the hippocampus and cochlear ganglion cells [106, 107].

Monoamine neurotransmitters, such as norepinephrine and dopamine, are elevated after CO exposure; enzymatic breakdown and auto-oxidation generate reactive O_2 species [108, 109]. These agents seem to contribute to oxidative stress after CO poisoning because free radical production in the brain can be diminished by inhibiting monoamine oxidase B, an enzyme located in microglial cells [110–112]. Nitric

oxide augments presynaptic release of monoamine neurotransmitters by activating NMDA receptors [113, 114]. Activated microglia also can mediate neuronal injury by generating •NO-derived oxidants [115]. Microglia can attack oligodendroglia and have been associated with demyelination processes [116]. •NO-mediated oxidative stress may be a common biochemical link among different pathways of CO poisoning.

Neuropathology after CO poisoning may include neuronal death in the cortex, hippocampus, substantia nigra, and globus pallidus [117]. One of the most common abnormalities is demyelination of the cerebral cortex, which occurs in a perivascular distribution along with evidence of a breach in the blood-brain barrier [117–119]. Blood flow and perivascular abnormalities have been shown using several neuroimaging techniques [120–125]. Acute vascular and perivascular changes also have been found in brains of experimental animals [44, 60, 64]. The variability observed in lesions found in the cerebral white matter and globus pallidus of animals has been correlated with the decrease in local blood flow and metabolic acidosis [58, 126]. Clinical and experimental findings suggest that the effects of CO are global, and variations in the clinical manifestations of poisoning arise because brain regions respond differently to the stresses. Acute neurologic compromise may be due to direct hypoxic stress. The syndrome of delayed neurologic sequelae seems to be a consequence of a cascade of events involving oxidative stress and inflammatory responses.

Clinical Effects

When CO enters the body via the lungs, pulmonary cells may be injured by direct interactions, without the need for delivery of CO by blood-borne hemoglobin. Elsewhere in the body, CO is delivered by hemoglobin, and concentrations found in perivascular and extravascular sites are estimated using calculations first described by Coburn (see Fig. 1) [50]. The symptoms, signs, and prognosis of acute CO poisoning correlate poorly with the level of

COHb measured at the time of arrival at the hospital [4, 61–66, 104]. These observations have created two concerns. The first is that investigators must be careful when attempting to study patient populations because determination of the severity of poisonings and the efficacy of treatment is difficult. The second concern is that these clinical observations raise questions regarding the mechanisms of toxicity beyond the classic perspective regarding hemoglobin binding by CO.

Neurologic symptoms of CO poisoning generally are more severe with higher COHb levels, including headache, dizziness, nausea, vomiting, weakness, confusion, disorientation, visual disturbances, and unconsciousness. Cardiac rhythm disturbances include sinus tachycardia, atrial flutter and fibrillation, premature ventricular contractions, ventricular tachycardia, and ventricular fibrillation. Myocardial infarction can occur, even among patients with normal coronary vessels [127, 128]. Pulmonary edema in association with CO is relatively rare; it typically occurs as a consequence of congestive heart failure. Pulmonary edema is seen more commonly in patients with concomitant smoke inhalation, and in these patients it may be related to inhalation of the myriad toxic combustion products [129]. Skeletal muscle necrosis can occur and with it acute renal failure. Other rare complications include pancreatitis and hepatocellular injuries. Textbooks often contain tables listing symptoms associated with different COHb levels. Practicing physicians should spend little time examining these lists, however, because the relationship between clinical presentation and COHb levels is extremely poor.

Patients may sustain neurologic abnormalities that are present during the acute hospitalization and either never resolve or resolve slowly over weeks to months after poisoning. Alternatively, patients may develop a delayed neurologic syndrome in which they manifest new cognitive deficits days to weeks after apparent recovery. These manifestations include impaired judgment, poor concentration, memory loss, and a relative indifference to obvious neurologic deficits (e.g., movement disorders, incontinence, speech

disturbances, parkinsonian syndrome, and, rarely, tremors).

Diagnostic Tools

Large clinical surveys reported a correlation between neurologic morbidity and the occurrence of an interval of unconsciousness during CO exposure [59, 81, 82]. This overt insult is not always necessary, however, for neurologic injuries to occur in humans [65, 70–72]. Using traditional neuroimaging techniques, such as computed tomography and magnetic resonance imaging, brain lesions have been detected sporadically in severely poisoned CO patients [130, 131]. The primary shortcoming with these imaging techniques is their limited sensitivity; neuroimaging has not yet provided a reliable method for assessing the severity of CO poisoning. Bianco and Floris [120] and Silverman and colleagues [125] hypothesized, however, that the initial site of injury by CO may be the vasculature, based on detection of hemosiderin deposits. These deposits are thought to result from focal hemorrhages.

More sophisticated neuroimaging techniques have been used to detect abnormalities in patients who, in some cases, exhibited only subtle neurologic impairments. Abnormalities in resting cerebral blood flow [123, 124] and abnormalities in cerebral vasoactivity to CO [122] have been detected by single-photon emission computed tomography. Changes also have been detected that suggest CO causes a disturbance in coupling between neuronal O₂ demand and blood flow. DeReuck and coworkers [121] examined seven patients 5–7 days after CO poisoning using positron emission tomography with ¹⁵O₂. They found a global increase in cerebral O₂ extraction along with regional areas of diminished blood flow, especially in the frontal and temporal lobes. Although these observations underscore the vascular nature of CO-mediated neuropathology, they do not assist with clinical assessments of patients. To date, no objective parameters that prospectively assess the severity of poisoning have been identified. Some more recent findings

with state-of-the-art neuroimaging techniques have exhibited correlations with the clinical improvement in case reports, whereas others show abnormalities when no clinical changes are noted [132–134]. In experimental studies, blood levels of glutathione, oxidized proteins, and products of lipid peroxidation offer insight into CO-mediated pathology [135]. Additional work is necessary, however, to establish if these or some other survey may be useful to stage the severity of clinical poisonings.

Treatment

As in any critical care setting, initial attention must be focused on restoring or maintaining vital functions. Preservation of a patent airway, ventilation, oxygenation, and adequate perfusion is the foundation for proper actions in serious CO poisoning. Emphasis is placed on O₂ treatment because the rate of COHb dissociation is proportional to the arterial O₂ partial pressure [136].

A great deal has been written about HBO₂ therapy for CO poisoning. HBO₂ therapy is a patient treatment modality in which a person breathes 100% O₂ while exposed in a treatment chamber to increased atmospheric pressure. Treatments typically are conducted at pressures two to three times higher than normal atmospheric pressure (14.7 psi) or 2–3 atm absolute (ATA). The hyperbaric chamber per se is not the therapeutic agent. Oxygen is the therapeutic drug, and the chamber is used as a dosing device. At ambient pressures, 100% oxygen reduces the half-life of COHb from about 320 to 85 min. Furthermore, at 2.5 ATA, the half-life is reduced to 20 min [137, 138].

Indications for ICU Admission in Carbon Monoxide Poisoning

Persistent depressed level of consciousness
Cardiac ischemia
Intercurrent critical illness (e.g., aspiration, acidosis, cotoxicants)

Since 1960, HBO₂ therapy has been used with increasing frequency for severe CO poisoning because clinical recovery has seemed to be improved beyond that expected with ambient pressure O₂ therapy [63, 67, 139]. No definition has been established for staging the severity of CO poisoning, however. It is difficult to evaluate patients in a prospective manner or compare the efficacy of different treatments. For this reason, studies that have selected a discrete, presumably more homogeneous, subset of patients may provide information that is more reliable.

Support for use of HBO₂ therapy comes from animal and a basic science experience and from nonrandomized comparative studies [58, 63, 139–144]. The initial motivation for administering HBO₂ therapy was to hasten the removal of CO, based on the well-known relationship that COHb half-life is inversely related to the inspired partial pressure of O₂ [136, 145]. Also, hyperbaric oxygen increases the total amount and concentration of dissolved oxygen by approximately ten times. This is sufficient to supply the body with its metabolic needs even in the absence of hemoglobin [146]. HBO₂ therapy also hastens dissociation of CO from cytochrome oxidase [75, 76] and inhibits cerebral edema in experimental CO brain injury [74, 100]. In rats poisoned with carbon monoxide which had subsequent loss of consciousness, hyperbaric oxygen was superior to normobaric oxygen in preventing brain lipid peroxidation [46]. Vascular oxidative stress is prevented because HBO₂ therapy inhibits β_2 integrin-dependent leukocyte adhesion [96, 147]. Neutrophils from humans exposed to HBO₂ exhibit the same diminished adherence as neutrophils in animal studies [148].

In 1969, a retrospective study reported that HBO₂ reduced mortality and morbidity only if administered within 6 h after CO poisoning [140]. In a prospective trial involving patients with mild-to-moderate poisoning, 23% of patients (7 of 30) treated with ambient pressure O₂ developed neurologic sequelae, whereas no patients (0 of 30; $P < 0.05$) treated with HBO₂ (2.8 ATA) developed sequelae [65]. HBO₂ therapy also was reported to have a significant benefit in

another prospective, randomized trial [122]. Twenty-six patients were hospitalized within 2 h of discovery and equally divided between two treatment groups: ambient pressure O₂ or 2.5 ATA O₂. Three weeks later, patients treated with HBO₂ had significantly fewer abnormalities on electroencephalogram, and single-photon emission computed tomography showed that cerebral vessels had nearly normal reactivity to carbon dioxide, in contrast to diminished reactivity in patients treated with ambient pressure O₂.

Mathieu et al. [68] reported on a large trial of HBO₂ therapy for CO poisoning ($n = 575$ patients). Among noncomatose patients who had experienced transient unconsciousness, those treated with ambient pressure O₂ had a higher incidence of delayed sequelae. Most sequelae spontaneously resolved over 6 months.

Due to the concern for the development of delayed neurologic sequelae, as well as for the relatively low risk of complications in the administration of hyperbaric oxygen, greater than 1000 patients receive this therapeutic each year in the United States [149]. There is a legitimate concern over the lack of reliable methods to assess the severity of poisoning. The use of HBO₂ therapy in every CO-poisoned patient who has had loss of consciousness during CO exposure or who has a neurologic abnormality on clinical examination continues to be advocated by some. In addition to its use for patients with transient unconsciousness and neurologic signs, some clinicians treat patients with HBO₂ when they have abnormal psychometric test results and if the COHb level is greater than a certain value. Some use a COHb of 40%, whereas others use 25%, regardless of symptoms [150, 151]. Important caveats regarding HBO₂ therapy include the observation that treatment efficacy, if any, may diminish if treatment is delayed for more than 6 h after poisoning [67, 140].

A large and growing body of clinical studies is showing that the benefits of HBO₂ in the setting of carbon monoxide poisoning is not as clear as demonstrated in animal and basic science experience. Some centers have proposed using a psychometric screening test to identify patients with

subtle neurologic compromise and as a method to stratify patients for treatment. However, this approach has not been empirically validated. When examined in a prospective study, abnormalities during the initial screening did not correlate with the development of delayed sequelae [65].

The first prospective clinical trial involving HBO₂ therapy did not find it to be superior to ambient pressure treatment [69]. Additionally, Scheinkestel et al. [152] performed a prospective trial of 191 patients and reported no benefit from administration of HBO₂ and ambient pressure O₂ therapy that extended over days. Concerns with this study include the following: There was a mean delay to treatment of 7.5 h, symptoms of O₂ toxicity occurred in the experimental group, and only 46% of patients who entered the study were assessed to evaluate delayed neurologic sequelae. A reevaluation of the subset of Scheinkestel's patients presumed to have mild CO poisoning demonstrates the difficult issues with patient evaluation and selection criteria. Using the "mildly" poisoned subset of patients, Kehat and Shupak [153] examined the difference in incidence of acute or persistent neurologic sequelae between the two treatment groups. Patients treated with HBO₂ had a significantly lower incidence of sequelae than patients treated with ambient pressure O₂.

A more recent investigation of 179 patients demonstrated that there was no benefit from a single hyperbaric oxygen treatment in those with a transient loss of consciousness. The authors showed that neurologic recovery after 1 month was the same (60%) regardless of whether or not the patients had hyperbaric oxygen or normobaric oxygen [154].

The threshold for using HBO₂ therapy, if any, has not been established clearly. Despite the widespread use of HBO₂ by some centers, a recent Cochrane review was not able to demonstrate a benefit to the use of hyperbaric oxygen in the setting of carbon monoxide poisoning. While no clear benefit was established, the possibility of a benefit was also not definitely ruled out [155]. Thus, the lack of consensus in the interpretation of the existing evidence is such that that hyperbaric oxygen should not be considered the standard of care at this time.

A small amount of evidence exists that patients presenting with a history of loss of consciousness or comatose are likely to benefit most from this therapy in an attempt to prevent delayed neurologic sequelae [156]. It is likely that syncope is secondary to the hypotension needed to initiate the neurologic damage in the setting of carbon monoxide poisoning. This has been demonstrated in animal models [58, 157]. Patients who present after long exposures to carbon monoxide (6 h or no longer) are also at risk of developing delayed neurologic sequelae [80]. In addition, patients with a metabolic acidosis or those with an alteration in level of consciousness to a GCS < 9 also had a greater risk of developing delayed neurologic sequelae. Another factor considered in determination as to whether hyperbaric oxygen should be considered is the development of myocardial ischemia. Despite these assertions, controlled trials show that in patients not treated with hyperbaric oxygen, no reliable factors at the time of presentation were found for predicting patients at risk to develop delayed cognitive sequelae [156]. In this analysis, age >36 years and carbon monoxide exposure >24 h of duration were associated with a greater risk of cognitive dysfunction at 6 weeks [156]. In one prospective study investigating carbon monoxide poisoning, cerebellar dysfunction is associated with a greater risk of cognitive sequelae [156]. Signs and symptoms currently used by many clinicians to determine the need for HBO₂ include syncope, neurologic dysfunction, seizure, cerebellar ataxia, coma, as well as alteration in mental status [158–160]. This is regardless of their carboxyhemoglobin concentration. It is noteworthy that patients who suffered cardiac arrest secondary to carbon monoxide poisoning and subsequently received hyperbaric oxygen all died [161]. If the decision is made to use HBO₂, the first consideration must be the logistical requirements of transporting a patient to a hyperbaric facility. One group examined this question in their review of 297 consecutive CO-poisoned patients and concluded that transfer need not be deferred because of a concern over cardiac or respiratory arrest, myocardial infarction, or deterioration in mental status if these events had not occurred

before transfer [162]. The potential adverse effects of HBO₂ therapy per se are rare, and they usually are mild and self-limited. Relative risks always must be considered in any therapeutic setting, however. Preexisting conditions that require some forethought and possible management before initiating HBO₂ therapy include patients with claustrophobia, sinus congestion, and scarred or noncompliant structures in the middle ear (e.g., in patients with otosclerosis) [163]. Middle ear barotrauma due to eustachian tube dysfunction may occur in 2% of patients and is managed easily by oral decongestants or rarely by tympanostomy tubes [164]. Transient nearsightedness, thought to be related to lenticular changes from O₂, occurs in association with treatment courses spanning weeks in approximately 33% of patients older than age 50. This risk is not a concern when treating CO poisoning because the course of therapy typically spans only one to three treatments. The visual changes resolve 3–6 weeks after treatments cease [163]. There are no notable pulmonary oxygen toxicity risks with therapeutic protocols [165–167] because the duration of exposure usually is kept to less than 2 h. Patients may have central nervous system O₂ toxicity, which is manifested as a grand mal seizure. In the general population, central nervous system O₂ toxicity occurs with a frequency of approximately 1 in 10,000, but among CO poisoning victims, it may be more frequent, possibly due to the direct effects of CO or to concomitant respiratory acidosis. Regardless, if mechanical trauma can be avoided during the convulsion, there are no residual effects [165]. Vasoconstriction is a physiologic effect of hyperoxygenation; this causes negligible changes in blood pressure because of a small (about 10%) decrease in cardiac output, principally caused by vagal stimulation with a reduction in heart rate [168]. Previous exposure to the chemotherapeutic agent bleomycin is considered a relatively strong contraindication to HBO₂ therapy. Bleomycin exacerbates pulmonary oxygen toxicity [169, 170]. On a case-by-case basis, careful consideration of this risk must be weighed against the potential benefits of HBO₂ therapy. The only well-recognized absolute contraindication for

HBO₂ therapy is an unvented pneumothorax, based on the risk of exacerbating this condition while in the hyperbaric chamber and especially on decompression.

Special Populations

Pregnant Patients

The clinical outcomes of CO poisoning for the mother and fetus do not correlate with maternal COHb concentrations. They do not accurately estimate fetal CO-hemoglobin concentrations or fetal CO tissue burden [171]. Maternal symptoms at the time of exposure are associated with fetal morbidity and mortality [172, 173]. In some series, the fetuses of severely symptomatic pregnant patients suffered stillbirths and cerebral palsy [174]. When mother and fetus survive, many fetuses subsequently develop somatic and neurologic sequelae, including malformations of limbs, hypotonia and areflexia, persistent seizures, mental and motor disabilities, and microcephaly [175, 176].

Hypoxic stress related to impaired O₂ delivery is an obvious component to fetal distress. Normal fetal arterial PO₂ is about 20 mmHg versus 100 mmHg for maternal arterial blood. The fetal O₂ exchange typically occurs near the steep portion of the oxyhemoglobin dissociation curve. A small decline in maternal PO₂ can cause a precipitous decline in fetal PO₂. This physiologic stress occurs more quickly than that associated with CO binding to fetal proteins. The decline in fetal arterial oxygen content occurs rapidly as CO concentrations approach 3000 ppm [175]. In studies with sheep, Longo and Hill [177] showed that fetal COHb does not reach steady state until approximately 36–48 h, whereas maternal COHb reaches steady state in 7–8 h. These sheep studies derived the popular notion that fetal hemoglobin has a higher affinity for CO than maternal hemoglobin. In vitro studies, however, demonstrate that fetal hemoglobin is 0.8 times the affinity for CO than maternal hemoglobin [178].

The second insult related to fetal COHb is a disturbance in the O₂-hemoglobin dissociation

curve. Binding by CO causes a left shift of the curve, which increases the hypoxic stress to the fetus. Fetal COHb concentration rises more slowly than does maternal COHb, but when steady state is reached, the fetal level is higher; this is related to the higher affinity fetal hemoglobin has for CO compared with hemoglobin A. The human fetal-maternal COHb concentration ratio is 1.1:1.0; that is, at steady state, the fetal COHb concentration is 10–15% higher than maternal COHb. Although the slow uptake kinetics may be viewed as a protective factor for the fetus, the dynamics work in reverse for CO elimination. In studies with sheep, the half-life for fetal COHb was nearly double that for maternal COHb [177]. For this reason, clinical recommendations for treating CO poisoning in pregnant women with ambient pressure O₂ suggest that pregnant women should breathe 100% O₂ five times longer than the time it takes for their own blood to register negligible residual COHb.

The current recommendations for use of HBO₂ therapy in pregnant women are essentially the same as the recommendations to treat any other patient. First, pregnant patients should receive 100% oxygen (typically by facemask). It is important to note that elimination of CO from fetal circulation is slower (approximately 3.5 times slower) than maternal circulation. Case series show that pregnant patients presenting without loss of consciousness or alteration in mental status go on to have uncomplicated deliveries [172, 178]. Some groups also treat based solely on an elevated COHb concentration. Anecdotal clinical reports suggest that HBO₂ therapy may improve fetal outcome [173, 178–183]. The only experimental study addressing the efficacy of HBO₂ for reducing fetal risk from acute CO poisoning showed a reduction in spontaneous abortion in pregnant rats [184]. There are no significant extra risks presented to the fetus or mother due to HBO₂ therapy [185, 186]. Therefore, hyperbaric oxygen may be considered for CO-poisoned pregnant patients who present with alterations in mental status and loss of consciousness. However, given that toddlers and infants have no abnormalities in reaching their developmental

milestones in normal appearing pregnant patients exposed to CO, similar considerations for hyperbaric oxygen therapy of all patients should apply to this group.

Pediatric Patients

Clinical signs and symptoms of CO poisoning in children are the same as in adults. Children may become symptomatic during CO exposures sooner than adults, however, owing to their higher metabolic rates, respiratory exchange requirements, and smaller blood volumes [187, 188]. Studies demonstrate that pediatric patients are potentially symptomatic at lower COHb concentrations than adults [189]. Children may present with vague symptoms of nausea, vomiting, and headache, and the condition may be misdiagnosed as gastrointestinal disease [190]. Delayed neurologic sequelae have been reported in children [191, 192], and there is a case report of hydrocephalus after CO poisoning [193]. Case series demonstrate that pediatric patients appear to have a decreased incidence of delayed neurologic sequelae compared to adults [194]. Though low, there is a risk of delayed neurologic sequelae. HBO₂ therapy should be considered in pediatric CO poisoning. The threshold for treating children is the same as for adults.

Common Errors in Cyanide Poisoning

- Failure to administer antidotal therapy rapidly when cyanide poisoning seems a likely possibility
- Failure to realize the potential for falsely elevated whole-blood cyanide concentrations when serum thiocyanate levels are above normal
- Forgetting that patients with cyanide poisoning can be cyanotic
- Failure to appreciate that cyanide poisoning can be delayed for many hours after exposure to nitriles
- Believing that all victims of cyanide poisoning must have bright red skin or blood
- Believing that hydrogen cyanide smells like bitter almonds to most persons
- Believing that cyanide impairs oxygen transport by hemoglobin or that cyanide poisoning produces a saturation gap in arterial blood

Indications for ICU Admission in Cyanide Poisoning

Patients symptomatic from cyanide poisoning
Patients who have been exposed to potentially toxic doses of nitriles – onset of cyanide poisoning may be delayed for longer than 12–15 h

The subject of cyanide poisoning brings consternation to most physicians because they consider it a rare disorder and are generally unfamiliar with the drugs used to treat it. However, thousands of workers undergo potential cyanide exposure every day (Table 1); some victims of smoke inhalation routinely cared for by intensivists experience cyanide poisoning, and cyanide compounds are easily obtainable for use as agents of suicide, homicide, or terror.

The clinical syndrome of cyanide poisoning resembles many other illnesses, and treatment with antidotes with which most physicians are unfamiliar usually must proceed quickly without laboratory confirmation of cyanide poisoning. To provide rapid and effective therapy, the physician must become familiar with the clinical presentation of and clinical clues to the diagnosis of poisoning by cyanide.

Three main sources of cyanide exist: hydrogen cyanide (HCN), inorganic cyanide salts, and cyanogens, which are compounds that release

cyanide or that undergo metabolism to cyanide after absorption. HCN and inorganic cyanide salts are discussed first and in most detail as these are of greatest clinical relevance. Nitriles, the most commonly encountered cyanogens, which can produce delayed-onset and prolonged cyanide poisoning, are discussed in a separate section at the end of this chapter.

Hydrogen Cyanide and Inorganic Cyanide Salts

Sources and Chemistry

Hydrogen Cyanide

HCN (boiling point 27.7 °C) exists as a gas or liquid at commonly encountered temperatures. An aqueous solution of HCN (prussic acid or hydrocyanic acid) also is available. Liquid HCN and solutions of prussic acid may release gaseous HCN into the surrounding air. Although a bitter almond odor is attributed to HCN, most persons describe the odor as pungent, musty, or metallic, and about 20% of the population does not easily detect the odor [1]. The senior author has administered HCN odor challenges to more than 400 firefighters; none of them thought the odor resembled almonds, and a consistent fraction of 25% were unable to detect any odor. These findings are similar to those previously reported [53]. These findings, along with rapid olfactory fatigue, make it possible for large numbers of victims to be ill from HCN without any alert from a strong, bitter almond odor.

Inorganic Cyanide Salts

Numerous inorganic cyanide salts are used commercially. The most common ones are sodium, potassium, and calcium cyanide. Sodium, potassium, and calcium cyanide are crystalline, white solids that are freely soluble in water.

Hydrogen Cyanide Formation from Cyanide Salts

Although cylinders or containers of HCN gas or liquid can release toxic amounts of HCN, most

accidental exposures to HCN result from reactions with cyanide salts. When most inorganic cyanide salts come in contact with mineral acids, large quantities of HCN are formed and are released into the atmosphere. Using potassium cyanide (KCN) and sulfuric acid (H₂SO₄) as an example:

Lethal amounts of HCN can result from mixing water-soluble cyanide salts with water. As an example with KCN:

The percentage of cyanide converted to HCN (pK_a 9.3) in aqueous solutions of cyanide salts depends on the pH of the solution. The pH of a cyanide salt solution must be kept above 10.5–11 to prevent formation and release of significant quantities of HCN. Deaths from inhalation or dermal absorption of HCN have occurred when workers contaminated with powdered inorganic cyanide salts continued to wear wet clothing rather than having completely undressed in decontamination showers [2].

Solid cyanide salts also can react with water vapor in ambient air to form HCN. Fumigation powders containing sodium cyanide (NaCN) or calcium cyanide (Ca(CN)₂) are sprinkled on floors or down rodent burrows. In the presence of water or water vapor, HCN is released and reaches lethal concentrations in air. In the case of Ca(CN)₂:

Smoke, including that from cigarettes, commonly contains HCN [3–5]. Combustion of almost any organic compound containing carbon and nitrogen can generate HCN under the correct conditions [6]. Cyanide poisoning may be a contributor to death from smoke inhalation, especially in fires involving plastics.

Pharmacokinetics

Absorption. HCN is extremely well absorbed by inhalation and can produce rapid collapse and

death within minutes at high concentrations [7–9]. Because HCN is nonionized and of low molecular weight, significant absorption can occur through the skin if high enough concentrations are present [10, 11].

After ingestion, most cyanide salts are absorbed rapidly from mucous membranes, being converted to HCN upon contact with water. Depending on the dose, the onset of symptoms may occur within minutes, with death occurring within minutes to longer than an hour. At times onset has been so sudden that victims have had time only for a warning cry before unconsciousness [110]. When cyanide salts are placed in capsules and prevented from contact with oral mucosa, onset of symptoms may be delayed for several minutes or longer, depending on the dose, though collapse may still occur within 1 min after significant ingestions [111].

Exposures of large areas of skin to solid cyanide salts or aqueous solutions can result in absorption of lethal quantities of cyanide across skin. The dermal absorption rate of cyanide increases as the pH of a cyanide solution decreases because of increasing fractions of cyanide being found as HCN at lower pH values [2].

Brief contact between small areas of skin and dry, powdered cyanide salts would not be expected to produce toxicity. However, prolonged skin contact with smaller skin areas still can produce toxicity [12]. Increased absorption occurs across abraded or burned skin [13]. Onset of symptoms following large acute skin exposures has been delayed for 30 min if decontamination has not been effective, such as when a worker continues to wear wet, contaminated clothing [2].

Distribution. At physiological pH, virtually all cyanide in the body exists as HCN, and *cyanide* is used synonymously with *HCN* in this chapter when referring to cyanide in the body. Cyanide distributes widely after absorption. Measurable cyanide concentrations are found in the liver, spleen, kidney, brain, heart, spinal cord, lung, and fetus after acute poisoning. Because cyanide is concentrated within erythrocytes by binding to normally low concentrations of methemoglobin (Fig. 1), cyanide's apparent volume of distribution varies depending on circulating methemoglobin

Fig. 1 Schematic diagram of cyanide's distribution and elimination. At physiologic pH, virtually all cyanide is present as hydrogen cyanide (HCN). HCN that has entered plasma after absorption is concentrated within red blood cells, at least in part by binding to the normally small amount of methemoglobin, which contains ferric (Fe^{3+}) iron. HCN also easily diffuses across cell membranes into various organs, where it binds to and inhibits many

enzymes, the most important being cytochrome oxidase. HCN binds to the binuclear center (copper and iron) of cytochrome oxidase to inhibit electron transport through this complex. This produces a decrease in oxygen consumption and, indirectly, a decrease in adenosine triphosphate formation. HCN is detoxified by transsulfuration to thiocyanate (SCN^-), which is excreted in the urine

concentrations and depending on whether such binding is saturated [14–16].

Metabolism. Humans detoxify cyanide by transferring sulfane sulfur to cyanide to form thiocyanate (SCN^-) (see Fig. 1). Thiocyanate undergoes renal clearance with an elimination half-life of about 2.7 days in persons with normal renal function [17].

The exact mechanism for cyanide's transsulfuration in vivo is controversial. Two main enzymes convert cyanide to thiocyanate. Rhodanese (thiosulfate sulfurtransferase, EC 2.8.1.1) is restricted to mitochondria and found in various tissues, especially the liver, kidney, and skeletal muscle [18, 19]. A reaction catalyzed by rhodanese in vitro involves the transfer of a sulfur atom from thiosulfate ($\text{S}_2\text{O}_3^{2-}$) to cyanide:

Another enzyme, β -mercaptopyruvate–cyanide sulfurtransferase (EC 2.8.1.2), resides in the liver, kidneys, and erythrocytes [19] and transfers

sulfur from mercaptopyruvate to cyanide to form SCN^- by the following reaction:

The aforementioned controversy surrounding in vivo cyanide transsulfuration revolves around several pieces of seemingly conflicting data. Although rhodanese was historically credited with cyanide's detoxification, thiosulfate – a substrate for rhodanese – is thought to be unable to penetrate the inner mitochondrial membrane where rhodanese is located [20, 21]. Ballantyne and others [19, 20, 22] suggested a paradigm whereby numerous sulfur sources are acted on by various sulfurtransferases, including rhodanese and mercaptopyruvate sulfurtransferase, to form sulfane sulfur, which then complexes with albumin in the blood. A nonenzymatic reaction of the sulfane–albumin complex with cyanide could account for thiocyanate formation. Other data suggest, however, that the sulfane–albumin complex seems to play a minor role in detoxification of

cyanide *in vivo*. In rats in which the blood has been replaced by a fluorocarbon emulsion, sodium thiosulfate still efficiently antagonizes cyanide [23]. In the absence of the blood or circulating albumin, cyanide's detoxification can be attributed only to sulfurtransferase reactions occurring in tissue sites other than the blood. Regardless of the exact mechanism explaining cyanide's transsulfuration, investigators agree that sulfur sources such as thiosulfate are required for and greatly accelerate conversion of cyanide to thiocyanate.

Cyanide's affinity for the cobalt ion (Co^{2+}) causes it to combine with hydroxocobalamin to form cyanocobalamin (see Fig. 1), which is excreted in the urine and bile. This route of detoxification normally plays a minor role in acute cyanide poisoning but serves as the basis of antidotal therapy with parenteral hydroxocobalamin [24].

Data on the rate at which toxic concentrations of cyanide are eliminated are limited because of inaccurate measurements of whole-blood cyanide concentrations that have been reported in poisoned patients owing to conversion of plasma thiocyanate to HCN during analysis (described later). Induction of methemoglobinemia, a treatment strategy, causes HCN to redistribute from tissues into the blood (decrease in apparent volume of distribution), producing changes in blood cyanide concentrations that do not reflect absorption or elimination. Schulz [16] wrote that because of limited availability of sulfane sulfur at endogenous concentrations, transsulfuration of cyanide is saturable, with an average elimination rate of 1 μg HCN/kg/min in an adult. Cole and Vesey, who reported decreases in elevated and accurately measured red blood cell and plasma cyanide concentrations after infusions of sodium nitroprusside were stopped, found that elimination appeared to be first order, with a half-life of about 30 min in the absence of sodium thiosulfate supplementation. When sodium thiosulfate was given, the elimination half-life decreased to about 10 min [25]. The cyanide levels were not high enough, however, to be associated with serious toxicity. The possibility of saturable elimination kinetics at higher cyanide concentrations cannot be excluded.

Pathophysiology

Cyanide inhibits more than 40 enzymes [20, 26, 27]. Cyanide's affinity for cytochrome oxidase in the mitochondrial inner membrane accounts for most toxicity. Cytochrome oxidase serves as the terminal enzyme in the electron transport chain responsible for oxidative phosphorylation and transfers electrons onto oxygen to produce water. After binding to the copper-iron binuclear center of cytochrome oxidase [28], HCN prevents electron transport, which inhibits oxidative phosphorylation and oxygen consumption [29]. Cyanide's ability to inhibit glutamate decarboxylase might produce a decrease in brain γ -aminobutyric acid concentrations and contribute to seizures [30].

A metabolic acidosis and decrease in oxygen consumption accompany serious cyanide poisoning. The metabolic acidosis is frequently incorrectly attributed to elevated circulating lactate concentrations resulting from glycolytic conversion of glucose to lactate in the presence of impaired oxidative phosphorylation. Unquestionably the glycolytic conversion of glucose to lactate is accelerated and becomes an important source of adenosine triphosphate (ATP) during cyanide poisoning, resulting in elevated lactate concentrations. However, ATP production via the conversion of glucose to lactate is not significantly acidifying [31–33]. Although the exact amounts of ATP and lactate generated in glycolysis vary with cellular pH and concentrations of available substrates [32], glycolytic production of lactic acid and ATP results in minimal production of protons regardless of pH [32, 34, 35].

An understanding of the generation of ATP in oxidative phosphorylation and of hydrolysis of ATP in metabolic processes explains metabolic acidosis in cyanide poisoning. Cells hydrolyze ATP to adenosine diphosphate and phosphate for energy, and ATP hydrolysis results in net proton production [36]. Conversely, in oxidative phosphorylation, there is a net consumption of protons during ATP synthesis. When homeostatic mechanisms are operating normally, a normal pH is maintained to a large extent because ATP is being hydrolyzed at the same rate that it is being synthesized via mitochondrial oxidative

phosphorylation; that is, proton production from ATP hydrolysis (including from ATP produced in glycolysis) is balanced by mitochondrial proton consumption during ATP synthesis in oxidative phosphorylation [34]. Oxidative phosphorylation is an important buffer of protons for this reason. When cyanide impairs the electron transport chain, and oxidative phosphorylation slows or stops, protons created by the cellular hydrolysis of preformed ATP and of ATP produced anaerobically in glycolysis are no longer buffered by aerobic ATP synthesis [32, 37]. Cyanide's binding to cytochrome oxidase impairs electron transport, resulting in a decrease in oxygen consumption and ATP production. Cells accelerate anaerobic glycolytic ATP production with the conversion of glucose to lactate. Although cellular and circulating lactate concentrations increase, the lactic acid is not responsible for acidosis. Rather, the acidosis occurs because cells hydrolyze ATP generated in glycolysis, producing protons [37], while the ability to buffer hydrogen ions via oxidative phosphorylation is impaired.

There are several reasons why cyanide poisoning is characterized mainly by dysfunction of the cardiovascular system and central nervous system. In the presence of acidosis and decreasing ATP concentrations from impaired oxidative phosphorylation, organs most sensitive to energy deprivation (brain, heart) suffer first. Cytochrome oxidase in the heart is also more sensitive to inhibition by cyanide [38]. Finally, cyanide concentrations are higher in the brain and myocardium than in other organs at the time of death [20].

The minimal concentration of HCN in air required to produce death in humans remains ill-defined because most acute fatal poisonings result from large exposures. Animal species vary in their sensitivity to cyanide, and data indicate that prolonged exposures to HCN concentrations greater than 90 ppm are incompatible with life [39]. In human cases of poisoning in which ambient HCN concentrations have been reported, headache, metallic taste, and other minor symptoms have developed after several minutes of exposure to air containing 10–30 ppm of HCN [39]. Death may occur within 1 h of continuous inhalational exposure to 100 ppm of HCN [20, 39]

and within several minutes of breathing more than 300 ppm of HCN. Humans have survived a 90-s exposure to 453–557 ppm of HCN (estimated) and a 3-min exposure to 500 ppm of HCN [8, 9]. Ballantyne [20] suggested that the inhalational 5-min median lethal concentration for HCN is 680 ppm and the 30-min median lethal concentration is 200 ppm.

A lethal oral dose of HCN (in solution) is estimated at 50 mg in an adult; the ingestion of 5 mL of 20% hydrocyanic acid has been fatal. The lethal oral doses of KCN or NaCN are estimated at 200–300 mg, but survival has followed much larger doses with intensive supportive care [40–42].

Clinical Presentation

Onset of symptoms of cyanide poisoning may occur within seconds after the inhalation of concentrated HCN gas or mucosal contact with inorganic cyanide salts. The inhalation of moderate HCN concentrations may not produce toxicity until minutes to hours into the exposure. Persons who are asymptomatic or only moderately symptomatic after the inhalation of HCN do not worsen after exposure is terminated. Delayed onset of symptoms after the inhalation of HCN does not occur. Absorption may be delayed after ingestion of cyanide sequestered in capsules, with peak symptoms not occurring for 20–40 min or so.

The main hallmarks of acute cyanide poisoning, which are nonspecific, are central nervous system and cardiovascular dysfunction and a metabolic acidosis. Central nervous system dysfunction ranges from anxiety to confusion, delirium, lethargy, coma, convulsions, and cerebral death. Large acute exposures may result in collapse into generalized seizures. Tachypnea may occur early in cyanide poisoning from initial stimulation of carotid body receptors by relatively low concentrations of cyanide. Lethal concentrations of cyanide rapidly produce apnea.

Cardiovascular toxicity early in cyanide poisoning is characterized by tachycardia and, at times, mild transient hypertension. As the illness progresses, hypotension, tachycardia,

bradycardia, heart blocks, ventricular arrhythmias, and asystole follow. Wexler and colleagues [43] described electrocardiographic changes in 16 men who received 0.2 mg cyanide/kg body weight intravenously. Sinus arrest lasting 0.88–4.2 s immediately preceded tachypnea and was thought to be vagally mediated. The periods of sinus arrest were followed by irregularities in sinus rhythms, with slowing of heart rates for periods of a few seconds to 2 min. There was gradual acceleration of heart rate to levels higher than control values. Wexler [43] also described electrocardiographic changes in four men executed by inhalation of HCN. They reported progressive shortening of the ST segment until, terminally, the T wave originated on the R wave. This “T-on-R” phenomenon has been described in other cases of cyanide poisoning [40].

Other common signs and symptoms in patients with cyanide poisoning include diaphoresis, weakness, nausea, and vomiting [44]. In serious poisoning, additional organ systems fail, leading to rhabdomyolysis, renal failure, hepatic necrosis, and adult respiratory distress syndrome [20, 41, 45].

The alkaline nature of granular cyanide salts or their aqueous solutions explains occasional corrosive injury when they come in contact with moist mucosal surfaces, especially the gastrointestinal tract [46]. Dermal injury also has followed acute skin contact with alkaline cyanide solutions [47].

Victims of cyanide poisoning may be left with permanent neurologic sequelae, including necrosis of the basal ganglia [48, 49]. Lesions in the basal ganglia are not specific for cyanide but are seen after severe hypoxemia or after poisoning by many metabolic toxins, including carbon monoxide, ethylene glycol, sodium azide, manganese, and methanol.

Diagnosis

When confronted with a case of suspected cyanide poisoning, physicians must make therapeutic decisions before results of cyanide levels are available. Certain historical points, physical findings, and general laboratory data must be used to seek evidence of cyanide poisoning.

Rapid collapse into coma or convulsions suggests the possibility of cyanide poisoning, but many patients may have gradual onset of symptoms over minutes to hours if exposures have been prolonged but not as intense, and toxicity may never become severe enough to produce coma. As noted earlier, the alleged bitter almond odor of cyanide is rarely noted, and it is possible for several persons in an exposure incident to die of cyanide poisoning without anyone complaining of or noting an abnormal odor. Even at autopsy on internal examination of the body, a bitter almond odor is not a reliable finding [46].

Many patients with serious cyanide poisoning are hypothermic. Depressed oxygen consumption from cyanide may produce an increased oxygen content of peripheral and mixed venous blood [50–52] if cardiac output is maintained. Bright red venous blood or retinal veins suggest the possibility of cyanide poisoning [53]. Most victims do not have unusually bright red skin or blood, however, and many victims exhibit cyanosis [49, 54, 55] because low cardiac output and intrapulmonary shunting in any patient with severe shock can cause arterial hypoxemia, despite low oxygen consumption. The absence of bright red skin or blood should never be used to exclude the possibility of cyanide poisoning.

An anion gap metabolic acidosis is always present in serious cyanide poisoning, unless the patient had a preexistent serious metabolic alkalosis or has received significant doses of sodium bicarbonate. Arterial lactate concentrations are elevated, but the lactate concentration does not always account for the entire increase in anion gap or base deficit because lactate is not actually responsible for acidosis (discussed earlier).

Cardiovascular and metabolic parameters obtained from invasive monitoring in patients with cyanide poisoning may reveal changes compatible with many disorders, including sepsis, toxic shock syndrome, or hepatic failure. Similar to cyanide poisoning, all of these conditions can produce metabolic acidosis, hypotension, decrease in oxygen consumption, increase in mixed venous oxygen content, decrease in the arterial-venous oxygen content difference, and

systemic vasodilation. Because baseline values (i.e., before cyanide poisoning) for oxygen consumption and mixed venous oxygen content are unknown for individual patients; because both parameters are influenced by cardiac output, which can vary from normal to increased early in cyanide poisoning to profound depression near death; and because both parameters depend on adequacy of oxygenation (e.g., adequate respiration, normal ventilation/perfusion), it is impossible to determine absolute cutoffs for oxygen consumption or mixed venous oxygen content that should strongly suggest cyanide toxicity. There are no studies examining the predictive values of these parameters for the diagnosis of cyanide poisoning. About the only statement that can be safely made is that a clearly normal or elevated oxygen consumption in a comatose patient does not suggest cyanide toxicity.

Claims [50, 56] that cyanide combines with hemoglobin to produce cyanhemoglobin and a difference between calculated arterial hemoglobin saturation and that measured by multiwavelength cooximetry (percent saturation gap) are unfounded and have never been documented. In fact, studies have shown that erythrocytes mixed with cyanide fail to show impaired oxygen carrying capacity until after a time that death would already have occurred [57], and cooximetry of whole blood containing lethal concentrations of cyanide does not show a percent saturation gap [58]. An unexplainable percent saturation gap is unexpected in patients with isolated and untreated (i.e., no methemoglobinemia) cyanide poisoning.

Cyanide Concentrations

The diagnosis of cyanide poisoning can be confirmed by measurement of circulating cyanide concentrations. Plasma cyanide is in equilibrium with tissue cyanide and correlates with tissue cyanide concentrations [15, 59]. In the blood, most cyanide is concentrated within red blood cells, making red blood cell cyanide concentrations many times higher than concentrations in plasma. The higher levels of cyanide found in red blood cells are more easily measured, and red blood cell cyanide concentrations correlate with

concentrations in plasma and tissue. Red blood cell cyanide concentrations are best used to confirm the diagnosis of cyanide poisoning.

Red blood cell cyanide concentrations of healthy adults are generally less than 29 $\mu\text{g/L}$ (1 $\mu\text{mol/L}$) [16]. In nonanemic patients with normal methemoglobin fractions, early metabolic disturbances from cyanide toxicity (e.g., metabolic acidosis) begin to appear at red blood cell cyanide concentrations of about 1 mg/L [60]. Obvious cyanide toxicity is apparent when red blood cell cyanide concentrations reach about 5 mg/L .

Plasma cyanide concentrations can be used to diagnose cyanide poisoning, but accurate measurement is difficult given the much lower levels and the high volatility of HCN, allowing HCN to escape into the atmosphere when the tube of the blood is opened for separation of plasma and cells. Wilson and Mathews [61] reported that plasma cyanide concentrations in healthy subjects averaged 4 $\mu\text{g/L}$ (0.15 $\mu\text{mol/L}$) in nonsmokers and 6 $\mu\text{g/L}$ (0.22 $\mu\text{mol/L}$) in smokers. Cottrell and colleagues [62] reported that mild metabolic acidosis developed in some patients receiving sodium nitroprusside under anesthesia when plasma cyanide concentrations reached approximately 30–35 $\mu\text{g/L}$ (approximately 1 $\mu\text{mol/L}$). Vesey and Cole [63] estimated the minimal lethal plasma cyanide concentration to be 243 $\mu\text{g/L}$ (9 $\mu\text{mol/L}$). Sheep dying from intramuscular potassium cyanide injections had plasma cyanide concentrations ranging from 900 to 2200 $\mu\text{g/L}$ (33–81 $\mu\text{mol/L}$) [20]. Because of difficulty in accurate measurement, plasma cyanide concentrations are best reserved for experimental studies in which collection, processing, and analysis are under tight quality control by personnel who regularly perform such measurements.

Measurements of *whole-blood* cyanide concentrations commonly offered by reference laboratories can fail to reflect accurate measurements of circulating cyanide. During acidification of whole blood during analysis, oxyhemoglobin released from red blood cells combines with thiocyanate in plasma to generate HCN *de novo* [14]. Falsely high whole-blood cyanide concentrations can result whenever plasma thiocyanate

concentrations are elevated significantly above normal (but not to toxic levels), even while cyanide concentrations are quite low or within the normal range. Examples of such situations in which this occurs are in patients receiving sodium nitroprusside infusions, patients with cyanide poisoning who have been treated with sodium thiosulfate for cyanide poisoning, and patients who have been exposed to cyanide and have successfully metabolized it to thiocyanate (with or without ever having experienced cyanide poisoning). Reported whole-blood cyanide concentrations may be higher than actual values and may easily mislead the physician into thinking that cyanide toxicity was present when it was not. Whole-blood cyanide concentrations generally should not be ordered unless their limitations are recognized when interpreting results. The potential for falsely elevated whole-blood cyanide levels also may contribute to the relatively wide range of upper boundaries for normal concentrations reported in the literature, ranging from about 0.05–0.5 mg/L (1.717 $\mu\text{mol/L}$).

Finally, cyanide concentrations can change during transportation and storage of tissue [1, 7, 64]. Several reports describe a decrease in cyanide concentrations in whole blood during storage, whereas others describe increases in cyanide content. The freezing and thawing of whole-blood specimens causes whole-blood cyanide concentrations to rise compared with prefrozen values [65]. The mechanism is probably mechanical hemolysis causing HCN formation from oxyhemoglobin and plasma thiocyanate during thawing. Whole-blood specimens should not be frozen during storage and transport.

Differential Diagnosis

The toxicologic differential diagnosis of cyanide poisoning is extensive and includes asphyxiation (e.g., inert gases, methane, nitrogen, carbon dioxide); poisonings by hydrogen sulfide and sulfide salts, methanol, ethylene glycol, pentaborane, azide, arsine, stibine, phosphine, phenol, cresol, methyl halides, and carbon monoxide; and, when cyanosis is present, methemoglobinemia. Any

illness characterized by sudden convulsions may be accompanied by hypotension, hypoxemia, and metabolic acidosis (e.g., poisoning by isoniazid or strychnine). Sudden unexpected collapse into unconsciousness or convulsions accompanied by metabolic acidosis and decreased oxygen consumption despite adequate oxygen delivery makes one lean toward the diagnosis of cyanide or sulfide poisoning.

Treatment

Pharmacologic Bases for Antidotal Strategies

The antidotal treatments described herein are based on practice in the United States. While the same antidotes are used widely around the world, we realize that there may be regional variation in antidotal practices and availability. In the United States, two antidotal strategies for treating cyanide poisoning are available: the combination of nitrite and thiosulfate and administration of hydroxocobalamin.

Nitrite and Thiosulfate

Parenteral delivery of sodium nitrite and sodium thiosulfate serves to induce methemoglobinemia and enhance conversion of cyanide to thiocyanate, respectively. Hydrogen cyanide binds to the binuclear iron–copper center of cytochrome oxidase to produce toxicity. Cyanide expresses low affinity for ferrous iron (Fe^{2+}) in hemoglobin. However, when iron of reduced hemoglobin is oxidized to the ferric state, methemoglobin is formed, and cyanide exhibits high affinity for Fe^{3+} in methemoglobin. Induction of methemoglobinemia with nitrite serves to create a large circulating sink of ferric iron that binds cyanide, allowing cyanide to dissociate from cytochrome oxidase in tissue and redistribute into plasma and into red blood cells, where it combines with methemoglobin to form cyanmethemoglobin (Fig. 2) [29].

Methemoglobin cannot carry oxygen and shifts the oxygen–hemoglobin dissociation curve to the left. The body has extensive mechanisms for maintaining methemoglobin fractions within

Fig. 2 Antidotal strategies in the treatment of cyanide toxicity with nitrites and thiosulfate. Hydrogen cyanide (HCN) binds to cellular cytochrome oxidase in tissues to inhibit oxidative phosphorylation. Sodium nitrite converts some ferrous hemoglobin (Fe^{2+}) to methemoglobin (Fe^{3+}), creating a large circulating sink of ferric iron. HCN quickly

dissociates from cytochrome oxidase and moves from tissue to bind to methemoglobin, forming cyanmethemoglobin and reversing inhibition of cytochrome oxidase. As cyanmethemoglobin is reduced back to Fe^{2+} , HCN is released. Sodium thiosulfate markedly enhances transsulfuration of HCN to thiocyanate (SCN^-)

erythrocytes at less than 1–2% (i.e., 1–2% of all heme pigments are in the met form). Methemoglobin fractions of 20–30% are tolerated, however, without life-threatening symptoms in otherwise healthy persons without anemia [66].

The historically recommended initial dose of sodium nitrite for nonanemic symptomatic adults with cyanide poisoning is 10 mL of a 3% solution (300 mg) intravenously over several minutes [67]. Several authors advocate methemoglobin fractions of 25–40% (assuming no anemia) to be most effective [68–70]. Much lower methemoglobin fractions are achieved, however, with the recommended dose of 300 mg of intravenous sodium nitrite [67, 68]. Peak methemoglobin fractions of 10.1% after 400 mg of intravenous sodium nitrite and of 17.5% after 600 mg of intravenous sodium nitrite were described by Moser [71]. Kiese and Weger [68] noted that methemoglobin fractions increased to a mean of 7% in six volunteers receiving intravenous sodium nitrite, 4 mg/kg. A single

volunteer developed a methemoglobin fraction of 30% after 12 mg/kg of intravenous sodium nitrite.

Methemoglobin fractions may not peak until 30 min after 4 mg/kg of intravenous sodium nitrite or until 60 min after 12 mg/kg of intravenous sodium nitrite, though they begin to rise immediately [68]. Despite the slow peak of methemoglobinemia after 300 mg of intravenous sodium nitrite, the combination of intravenous sodium nitrite and sodium thiosulfate remains superior to more rapid methemoglobin-forming agents such as 4-dimethylaminophenol [21] possibly because of a more sustained methemoglobinemia produced by sodium nitrite. The fact that dramatic improvements in symptoms have occurred well before methemoglobin levels have peaked [51, 72] also suggests that mechanisms other than methemoglobin production may be important in nitrite's antidotal action [21, 73]. Recent animal data suggest nitric oxide can overcome cyanide inhibition of cytochrome c oxidase, offering a

Fig. 3 Antidotal strategy in the treatment of cyanide toxicity with hydroxocobalamin. Hydrogen cyanide (HCN) binds to cellular cytochrome oxidase to inhibit oxidative phosphorylation. Hydroxocobalamin combines with cyanide, mainly in extracellular fluid, to form cyanocobalamin, which is excreted in the urine

possible contributing mechanism for sodium nitrite's antidotal effects [74–76].

Sodium thiosulfate (a source of sulfane sulfur) enhances conversion of cyanide to thiocyanate. The recommended dose is 12.5 g intravenously over a few minutes. Although methemoglobinemia can rapidly reverse serious cyanide poisoning, cyanide eventually is released from cyanmethemoglobin as this pigment is reduced to hemoglobin [77]. Coadministration of sodium thiosulfate with sodium nitrite enhances transsulfuration of cyanide that is unbound or that is released from cyanmethemoglobin to thiocyanate. Thiocyanate is of low-order toxicity and undergoes renal elimination with a half-life of 2.7 days in patients with normal renal function. The combination of sodium nitrite and sodium thiosulfate increases the required lethal dose for cyanide 13 times in some animal models, whereas lethal dose increases of 3–4 times are noted when each agent is given alone [78].

Some animal data suggest that vasodilation from nitrites might be beneficial in treating cyanide poisoning. α -Adrenoceptor antagonist vasodilators (e.g., phenoxybenzamine, chlorpromazine) enhance antidotal effects of thiosulfate in animal models of cyanide poisoning but have little action by themselves [79, 80]. Similarly, injection of erythrocytes exposed to nitrite *in vitro* (to produce methemoglobin) that are then washed free of excess nitrite

provides a degree of protection equivalent to that produced by nitrite directly injected into animals poisoned with cyanide, indicating that vasodilation plays a relatively unimportant role in explaining nitrite's antidotal action compared with methemoglobin induction [77].

Hydroxocobalamin

Hydroxocobalamin, the second approved antidotal therapy in the United States and used widely in other countries, exploits cyanide's affinity for cobalt. Hydroxocobalamin (Vitamin B_{12a}) combines with cyanide to form cyanocobalamin, which is excreted in the urine [24] (Fig. 3). Hydroxocobalamin's low apparent volume of distribution (0.45 L/kg) suggests mainly an extracellular site of action, and its elimination half-life in smoke inhalation victims averaged about 26 h [81].

In a dog model of acute cyanide toxicity, treatment with hydroxocobalamin (75 mg/kg or 150 mg/kg) was associated with increased survival (79% and 100%, respectively) compared to placebo (18%) [82]. Survival benefit has also been shown for hydroxocobalamin compared to placebo (73% versus 0%) following cyanide-induced cardiac arrest in pigs [83]. In some, but not all, animal models, the addition of intravenous sodium thiosulfate to hydroxocobalamin therapy

enhances antidotal activity of hydroxocobalamin, but thiosulfate must be infused separately [84].

In comparing hydroxocobalamin with nitrite-based antidotes in cyanide-poisoned swine, Bebart and Tanen found that hydroxocobalamin (150 mg/kg) with sodium thiosulfate (413 mg/kg) was associated with a faster return to baseline mean arterial pressure than sodium nitrite (10 mg/kg) with sodium thiosulfate, but there was no difference in mortality or other clinical parameters [85].

As is the case for sodium nitrite, neither randomized controlled trials of hydroxocobalamin in humans with cyanide poisoning nor human trials comparing hydroxocobalamin and other antidotes exist. Only uncontrolled and unblinded case series have been published. For example, Borron et al. [86] reported eight of 12 patients with known or suspected cyanide salt ingestions survived after treatment with hydroxocobalamin (5–20 g). An obvious advantage of hydroxocobalamin (and cobalt-EDTA and sodium thiosulfate) is lack of methemoglobin induction, which could be advantageous in treating severely anemic patients or those patients with cyanide poisoning from smoke inhalation, who also may have concomitant carbon monoxide poisoning. Borron et al. reported uncontrolled, unblinded observations on the use of hydroxocobalamin (median dose 5 g, maximum 15 g) for suspected cyanide toxicity after smoke inhalation [87]. In patients with what were reported to be toxic ($>39 \mu\text{mol/L}$) and lethal ($>100 \mu\text{mol/L}$) *whole-blood* cyanide levels, survival was 74% and 62%, respectively. The lack of control groups makes it impossible to know whether the treatment with hydroxocobalamin was effective in this setting. A French study of prehospital use of hydroxocobalamin for presumed cyanide toxicity after smoke inhalation found an overall survival rate of 41.7%, highlighting the generally poor outcomes typical for critically ill smoke inhalation victims [88].

Hydroxocobalamin produces bright red discoloration of the skin, urine, and plasma [89]. Plasma discoloration may interfere unpredictably with various chemistry laboratory analyses, including AST, bilirubin, creatine kinase, iron, and

magnesium [90–92]. Hydroxocobalamin also impedes accurate measurements of carboxyhemoglobin, methemoglobin, and oxyhemoglobin by cooximetry, which could have significant implications on management of smoke inhalation victims [92–94]. The magnitude of the interference depends on the specific cooximeter and may vary with carboxyhemoglobin and hydroxocobalamin concentrations. Hydroxocobalamin-induced discoloration of body fluids may have consequences extending beyond laboratory misinterpretation. There exists at least one case report describing hemodialysis malfunction after administration of hydroxocobalamin due to a “blood leak” alarm triggered by discolored body fluids [95].

Hydroxocobalamin has been shown to raise blood pressure after initial administration, commonly a desired effect in cyanide toxic patients. Other reported side effects comprise rare allergic reactions including urticaria, edema, and anaphylaxis [24].

Other Antidotes

Amyl nitrite inhalation has been used in the past for treatment of cyanide poisoning but is relatively ineffective as a methemoglobin-producing agent as compared to intravenous sodium nitrite [67]. Thus, its use has been abandoned in the United States, but remains in use in the prehospital setting in other countries.

Inhalation of 100% oxygen (along with nitrite and thiosulfate or hydroxocobalamin antidote) enhances survival over breathing room air in animals, but no advantage of hyperbaric oxygen therapy over the administration of 100% oxygen at 1 atm has been shown [96].

Cobalt-EDTA (ethylenediaminetetraacetic acid), a chelator of cyanide that then undergoes renal elimination, has been used in some countries [97]. It is available in 20-mL ampules, each containing 300 mg of cobalt-EDTA. The recommended dose is one ampule (300 mg) intravenously over 1 min. Repeat doses can be given after 1 and 5 min if there is no response, and slower infusion rates should be allowed for noncritically ill patients. The main side effect seems to be an anaphylactoid reaction, which can be life-threatening.

Cobinamide, a water-soluble analog of hydroxocobalamin, is currently under investigation as an alternative antidote that would not necessarily require intravenous administration. An intramuscularly administered antidote is desirable in the prehospital setting, particularly when intravenous access is difficult. Additionally, cobinamide contains two cyanide-binding sites and neutralizes 2 mol cyanide per mole compared with 1 mol cyanide per mole for hydroxocobalamin and is, thus, more potent. A swine model demonstrated intravenous cobinamide to be as effective as hydroxocobalamin at one fifth the dose for return of spontaneous breathing after acute cyanide poisoning [98].

Precursors to beta-mercaptopyruvate, including those that can be administered orally, are effective cyanide antidotes in animals and work by accelerating conversion of cyanide to thiocyanate by beta-mercaptopyruvate sulfurtransferase [99]. None are available for use in humans at present.

Vasodilation and hypotension produced by nitrites has, in part, led investigators in the armed services and in other countries to examine other methemoglobin-forming agents for the treatment of cyanide poisoning [69, 100]. DMAP (4-dimethylaminophenol) induces methemoglobinemia more rapidly than nitrite, but toxic side effects limit its use [100, 101].

General Management

Patients who are symptomatic after the inhalation of HCN do not require decontamination. A person who has inhaled HCN without becoming seriously ill is not in danger of developing delayed onset of more serious symptoms after exposure is terminated [7]. After removal from exposure, no decontamination is required after exposures to HCN gas other than removal of outer layers of clothing if exposure has just occurred.

Patients who have undergone significant skin contamination with solid cyanide salts or solutions may serve as a threat to rescuers and treating medical personnel. *All* clothing (including shoes or boots) should be removed, and the victim should be thoroughly decontaminated with copious volumes of water before entering a hospital. Inadequate decontamination results in generation

of HCN from water and remaining cyanide salts, with potential for off-gassing of HCN or delayed absorption of HCN through the skin.

Patients who have ingested cyanide salts and who have remained asymptomatic for 1–2 h would not be expected to become ill. It seems unlikely that activated charcoal could be given quickly enough after oral ingestion of cyanide to change the clinical course of cyanide poisoning. Distending a patient's stomach with a solution of charcoal when the patient may become unconscious or begin convulsing at any moment may promote vomiting and pulmonary aspiration. Gastric emptying by lavage is not known to be effective and generally is not recommended.

Symptomatic patients who have ingested cyanide salts may regurgitate HCN gas. Mouth-to-mouth ventilation is not recommended in such instances. The odor (usually poorly described) of HCN can be noted sometimes around the mouth of comatose patients who have ingested cyanide compounds, but there has never been a death or severe illness from inhalation of HCN in a person who has cared for such a patient, although mild symptoms (nausea, light-headedness) have been claimed. A letter to the editor claimed that mouth-to-mouth resuscitation of a cyanide-poisoned dog produced coma in the rescuer [102].

Antidotal Therapy

After addressing airway, ventilation, and circulation, efforts should be directed immediately toward antidotal therapy in symptomatic patients. There are two commercially available cyanide antidotes in the United States from which to choose. First, Nithiodote[®] (Hope Pharmaceuticals, Scottsdale, AZ) contains one 10 mL vial of 3% sodium nitrite (300 mg) and one 50 mL vial of 25% sodium thiosulfate (12.5 g) for intravenous injection. Each of these agents also may be purchased individually. Second, hydroxocobalamin is commercially available as Cyanokit[®] (Meridian Medical Technologies, Columbia, MD), which contains one vial of 5 g lyophilized hydroxocobalamin [103]. Other preparations/brands of sodium nitrite/sodium thiosulfate combinations or hydroxocobalamin are available in other countries, with generally similar dosing recommendations.

Antidotal Therapy for Cyanide Poisoning

As soon as an intravenous line is established, choose therapy #1 or therapy #2:

1. Nitrite/thiosulfate therapy:
 - a. 300 mg sodium nitrite (10 mL of 3% solution) intravenously. For critically ill patients, infuse over 2–3 min. For less severely poisoned patients, infusion can be over several minutes to limit hypotension (for children, give 0.2 mL/kg of 3% sodium nitrite).
 - b. Next infuse 12.5 g of sodium thiosulfate (50 mL of a 25% solution) intravenously over 2–5 min (for children, give 1 mL/kg of 25% solution).
2. Hydroxocobalamin therapy
 - a. 5 g hydroxocobalamin over 15 min (for children, give 70 mg/kg body weight)

As soon as an intravenous line is established, one of the two antidote therapies should be given, as described in detail below:

Nitrite/Thiosulfate Therapy

Ten mL of a 3% solution of sodium nitrite (300 mg) should be given intravenously. For moribund patients, the sodium nitrite can be given over 1–2 min. For less severely ill patients, it can be given more slowly to prevent significant falls in blood pressure. The administration of an entire ampule (10 mL) of 3% sodium nitrite to a small child potentially may produce lethal methemoglobinemia [70]. The same is true for adults with severe anemia. Children without anemia can receive 0.2 mL of 3% sodium nitrite/kg body weight, up to 10 mL.

After the administration of intravenous sodium nitrite, immediately give 50 mL of 25% sodium thiosulfate intravenously to adults over several minutes. The pediatric dose is 1 mL of 25% sodium thiosulfate/kg body weight [70].

Doses of sodium nitrite and sodium thiosulfate can be repeated if signs of cyanide poisoning (e.g.,

metabolic acidosis with coma) persist for 30 min or recur. In our experience, methemoglobin fractions remain less than 20% in nonanemic adults who received two doses of 300 mg of sodium nitrite given within 10 min, and this is in keeping with data by Moser [71]. If cooximetry is readily available, however, total hemoglobin and methemoglobin concentrations should be quickly measured before repeating a dose of sodium nitrite to ensure that dangerous methemoglobinemia will not occur, especially in children.

The best available data for use of sodium nitrite and thiosulfate in the treatment of cyanide toxicity constitutes level III evidence.

Hydroxocobalamin Therapy

Five grams lyophilized hydroxocobalamin should be reconstituted in 200 mL normal saline or another crystalloid and given intravenously over 15 min. In severely ill patients or those with insufficient clinical response to the initial treatment, a second dose of 5 g may be administered over 15 min (for patients in extremis) to 2 h for a total of 10 g. Children should receive 70 mg hydroxocobalamin per kg body weight for each dose.

Some toxicologists would immediately follow hydroxocobalamin administration with 12.5 g sodium thiosulfate intravenously, but it is not known whether this adds any benefit to adequate doses of hydroxocobalamin.

The best available data for use of hydroxocobalamin in the treatment of cyanide toxicity constitutes level III evidence.

Pediatric Doses of Cyanide Antidotes

Intravenous sodium nitrite and sodium thiosulfate

- If child is ill and not known to be anemic, give 0.2 mL/kg 3% sodium nitrite intravenously up to initial dose of 10 mL.
- Give 1 mL/kg 25% sodium thiosulfate solution.

Intravenous hydroxocobalamin

- Give 70 mg/kg hydroxocobalamin.

When patients remain seriously ill after maximal doses of one of the antidotal strategies, it is reasonable to add the alternative strategy. For example, if metabolic acidosis and coma remain after two doses of nitrite/thiosulfate therapy and methemoglobin fractions are approximately 25%, then administration of 5 g hydroxocobalamin is a reasonable addition. Conversely, if 10 g hydroxocobalamin have been given and the patient remains critically ill with metabolic acidosis, then administration of the nitrite/thiosulfate antidote is acceptable.

Treatment is otherwise supportive. Severe metabolic acidosis may require treatment with sodium bicarbonate. Rhabdomyolysis is treated by ensuring a brisk urine output and keeping the urine pH above approximately 6.0.

Special Populations

Cyanide toxicity in patients receiving sodium nitroprusside is discussed in the chapter on that topic.

Smoke Inhalation and/or Severe Anemia

When treating cyanide poisoning in the presence of concomitant carbon monoxide poisoning or severe anemia, hydroxocobalamin and/or sodium thiosulfate can be given without concern for further impairing oxygen delivery by induction of low-grade methemoglobinemia. However, there are no studies showing effectiveness of such therapy or trials that compare nitrite with other antidotes in this setting. Of note, red discoloration of hydroxocobalamin has been reported to produce falsely low carboxyhemoglobin readings by multiwavelength cooximetry [94]. This complicates the diagnosis of carbon monoxide poisoning if hydroxocobalamin is given before the blood is drawn for cooximetry studies and can prevent following serial carboxyhemoglobin fractions during oxygen therapy.

Pregnant Patients

As a small lipophilic molecule, HCN distributes easily to most organs, including the fetus. In fact, newborns of smoking mothers have higher blood

cyanide concentrations than newborns of nonsmoking mothers [104]. No studies have examined the efficacy or toxicity of sodium nitrite, sodium thiosulfate, or hydroxocobalamin in pregnant women. No guidelines exist for dosing of sodium nitrite to pregnant women with cyanide poisoning, although maternally administered sodium nitrite produces methemoglobinemia in the fetus [105]. In third-trimester gravid ewes with cyanide toxicity from sodium nitroprusside infusions, the administration of sodium thiosulfate prevents increases in circulating fetal cyanide concentrations, even though thiosulfate does not appear to cross the placenta [106]. This finding is best explained by the ability of thiosulfate to keep maternal cyanide levels low, allowing for cyanide to diffuse back out of the fetus into the maternal circulation for detoxification. In 2010, the US Food and Drug Administration approved hydroxocobalamin for use in pregnant women with cyanide toxicity. Dosing in pregnancy is unchanged from adult guidelines for hydroxocobalamin [103]. Given limited available data, pregnant patients with cyanide poisoning should be treated similarly to other patients. Fetal health is best ensured by ensuring the survival of the mother.

Cyanogens

Cyanogens are natural or synthetic compounds that, after absorption, undergo metabolism to release HCN (Table 2). (The term *cyanogen* also is used as a synonym for ethanedinitrile.) Nitriles (R-C-CN) and sodium nitroprusside account for most toxic exposure to synthetic cyanogens. Cyanide glycosides (e.g., amygdalin) are found naturally in many foods and plants. Because ► [Chap. 40](#), “Sodium Nitroprusside” is discussed in its own chapter and cyanide glycosides are discussed in ► [Chap. 112](#), “Cardiotoxic Plants”, the toxicity of nitriles is emphasized in this section. Nitriles are used as solvents, as intermediates in chemical synthesis, in nylon production, and for other purposes. Acetonitrile was commonly used in artificial fingernail glue remover, with tragic results in children who accidentally ingested these products.

Clinical Presentation

Nitriles can be absorbed by inhalation, through dermal contact, or after ingestion. Poisonings by nitriles differ, however, from poisonings by inorganic cyanide salts and HCN in three general ways. First, there may be a delay between exposure and the onset of symptoms for many hours, because hours may be required for nitrile metabolism to release enough HCN to produce symptoms. Second, because of continued metabolism of nitriles, HCN production and symptomatic cyanide poisoning may continue for hours to days, requiring prolonged antidotal therapy. Third, nitriles themselves possess toxicologic properties beyond those of HCN production, including mucosal irritation, nephrotoxicity, and peripheral neurotoxicity. Different nitriles vary as to whether most of their toxicity is explained by HCN release or by other toxic effects. These principles are best illustrated by briefly reviewing published examples of nitrile poisoning.

Muraki and colleagues [107] described a 35-year-old man who became ill 15 h after cleaning the inside of a reactor kiln with acetonitrile. Initial symptoms were nausea, vomiting, and weakness. More than 20 h after exposure, he had a convulsion and depressed level of consciousness with severe metabolic acidosis (pH 6.55; PCO_2 31 mmHg). Treatment eventually was instituted with sodium nitrite and sodium thiosulfate. The patient required mechanical ventilation and developed acute tubular necrosis from severe rhabdomyolysis (peak serum creatine kinase 325,000 IU/L) but eventually recovered completely.

Mueller and Borland [108] reported a 39-year-old woman who deliberately swallowed acetonitrile. Symptomatic cyanide poisoning developed 11 h later and was treated successfully with repeated doses of sodium nitrite and sodium thiosulfate. The half-life of acetonitrile was 40 h, and antidotal therapy was required for more than 24 h, with good outcome.

Treatment

Because patients who have ingested cyanogens such as acetonitrile may experience the onset of cyanide poisoning several hours after exposure (e.g., inhalation, ingestion), they should be observed closely for 24 h in the hospital in a monitored setting with cyanide antidotes readily available. Theoretically, activated charcoal might prevent absorption of cyanogens, and it might be reasonable to administer charcoal to such patients if they can be treated soon after ingestion. The disadvantage of distending a patient's stomach with a suspension of charcoal when the patient is at risk for rapid deterioration, convulsions, vomiting, and aspiration must be weighed against theoretical benefits that have not yet been shown in human studies.

Patients should be regularly evaluated at the bedside for evidence of cyanide poisoning. The onset of significant changes in vital signs, the onset of metabolic acidosis, or the voicing of new complaints (nausea, weakness, dyspnea) should warrant treatment of presumed cyanide poisoning with sodium nitrite and sodium thiosulfate or hydroxocobalamin, as in acute poisoning by inorganic cyanide compounds.

No studies provide guidance as how to repeat cyanide antidotes after initial dosing to symptomatic patients after nitrile exposure. After initial doses, it seems reasonable to provide a continuous infusion of sodium thiosulfate to enhance cyanide transsulfuration as it is being produced. At our center, we have infused 1.2 g/h of sodium thiosulfate for 24 h to such patients with good results and based this dose on a known safe constant infusion dose used in sodium nitroprusside therapy. More severely ill patients might require larger doses, however. If patients

experience recurrence of symptoms despite sodium thiosulfate infusion, it also seems reasonable to give repeated doses of sodium nitrite so as to maintain methemoglobin fractions between 7% and 25% or to repeat doses of hydroxocobalamin, but exact dosing schedules have not been studied or described.

With regard to acrylonitrile toxicity, studies suggest that an infusion of *N*-acetylcysteine, such as when used for acetaminophen toxicity, may be beneficial in promoting metabolism by a pathway that does not lead to cyanide release [109]. No controlled human studies have shown the benefit to such therapy, however.

Key Points in Cyanide Poisoning

1. In the body, virtually all cyanide exists as hydrogen cyanide (HCN).
2. HCN binds to cytochrome oxidase of the electron transport chain on the inner mitochondrial membrane to prevent oxygen consumption and electron transport, impairing adenosine triphosphate formation.
3. Rapid collapse with central nervous system dysfunction (coma, seizures, confusion), metabolic acidosis, and cardiovascular changes (hypotension, tachycardia) suggests the diagnosis of cyanide poisoning.
4. Other clues to diagnosis are hypothermia, occasionally bright red venous blood or retinal veins with cherry-red skin (but cyanosis also is common), elevated mixed venous oxygen content, and impaired oxygen consumption. Cyanide is not detected on routine urine or plasma drug screens.
5. HCN does not smell like bitter almonds to most persons, and it is possible for a group of victims to have cyanide poisoning without anyone noting a bitter almond odor.
6. In the United States, the traditional antidotal strategy is based on inducing methemoglobinemia with nitrites (to bind HCN) and enhancing cyanide's metabolism to

thiocyanate with sodium thiosulfate. An alternative strategy is administration of hydroxocobalamin to bind to HCN. No well-designed studies have compared these strategies in human beings.

7. If cyanide levels are measured, red blood cell cyanide levels are most helpful. Plasma cyanide concentrations are difficult to measure accurately. Whole-blood cyanide concentrations, which are offered by most laboratories, can be falsely elevated in several situations. Unless specimens are handled, stored, and transported correctly and analyzed in a timely manner, reported values for whole-blood or plasma cyanide may not reflect concentrations that were present when the specimen was obtained.
8. Nitriles such as acetonitrile or acrylonitrile are metabolized slowly to HCN after inhalation, ingestion, or skin contact. Cyanide poisoning may not appear for hours after exposure and may persist for 1–2 days.

Criteria for ICU Discharge in Cyanide Poisoning

Patients who were symptomatic from exposure to inorganic cyanide compounds or hydrogen cyanide:

- No antidotal therapy (hydroxocobalamin, nitrites, or thiosulfate) given in last 12 h
- No signs or symptoms of cyanide poisoning (e.g., no metabolic acidosis, normal vital signs)

Patients exposed to nitriles or other cyanogens:

- If never symptomatic, at least 24 h must have passed since exposure.

(continued)

- If patient developed signs and symptoms of cyanide poisoning, at least 24 h must have passed since patient has received any cyanide antidotes, and the patient must have remained asymptomatic during this time without antidotal therapy.

Hydrocarbons are a diverse group of chemicals made up of carbons and hydrogens that are the building blocks of life. Because they are ubiquitous, they are found not only in plants and animals but also in alcohols, solvents, natural gas, petroleum derivatives, and many industrial chemicals. In 2013, the National Poison Data System, a database maintained by the American Association of Poison Control Centers, reported 33,025 hydrocarbon exposures and 18 deaths. Eighty-five percent of all exposures were classified as unintentional, and 29% occurred among children less than 6 years of age [1]. Because not all exposures are reported to poison centers, this number certainly under represents the actual incidence of hydrocarbon exposures. Also, many low dose chronic hydrocarbon exposures cause toxicities, including cancer, that are most often seen by providers other than medical toxicologists. This chapter focuses on the critical care toxicology of hydrocarbon exposures; therefore, most of the chronic toxicities will not be discussed.

Biochemistry and Clinical Pharmacology

Hydrocarbons are divided into two main categories: aliphatic (straight-chain or branched-chain) and aromatic (cyclic hydrocarbons with resonating double bonds); for example, propane is aliphatic whereas benzene is aromatic (Fig. 1). Polyaromatics are composed of at least three

Sample Hydrocarbons:

Fig. 1 Sample hydrocarbons

benzene rings such as in benzopyrene. Alicyclic hydrocarbons consist of carbon chains in a ring structure (but do not contain resonating ring structure such as in benzene) that function similarly to aliphatics; an example is cyclohexane. Halogenated hydrocarbons contain halogen atoms (fluorine, chlorine, bromine, or iodine) in place of hydrogen atoms; an example is lindane (hexachlorocyclohexane). Saturated hydrocarbons have only single covalent bonds between their carbons, whereas unsaturated hydrocarbons contain double (alkenes) or triple (alkynes) bonds between adjacent carbons.

The physical state of hydrocarbons depends primarily on the size of the molecule. Methane, ethane, propane, and butane have chains that are 1, 2, 3, and 4 carbons long, respectively, and exist as gases at standard temperature and pressure. Hydrocarbons that contain 5–20 carbon atoms exist as liquid, and those that are more than 20 carbon atoms are semisolid or solid at standard temperature and pressure.

Physical properties of hydrocarbons play a crucial role in determining toxicity after ingestion: compounds with low surface tension and low viscosity have higher chance of spreading into the trachea during swallowing (higher risk of aspiration), and those with high volatility have greater tissue penetration and surfactant disruption (greater lung damage) [2]. Surface tension is the cohesion of molecules as generated by van der Waals forces; low surface tension allows them to spread rapidly over the contacted surface making them more easily aspirated. Viscosity is the resistance of a fluid to flow; low viscosity means the fluid flows more easily and allows for deeper penetration into the distal airways. Volatility is the tendency of a liquid

to vaporize into a gaseous state; increased volatility (smaller molecule size) enables easier generation of gas that can be inhaled deeper into the airways. This enhances tissue and cell membrane penetration and surfactant disruption.

When intentionally inhaled for recreational purposes, these hydrocarbons are considered inhalants. The US National Institute of Drug Abuse classifies inhalants into volatile solvents, aerosols, gases, and nitrites. Volatile solvents are a group of liquids with relatively high vapor pressures and include glues, fuels, paint thinners, and liquid in felt-tip markers. Vapor pressure is the force exerted by the vapor (substance in a gas phase) above a liquid surface; the higher the vapor pressure, the more likely it will overcome the atmospheric pressure and vaporize. Substances with high vapor pressure are considered volatile. Aerosols consist of sprays that contain both propellants and solvents and are often included in personal hygiene products such as hair sprays and deodorants. Propellants are pressurized gases, generally hydrocarbons, used in creating movement of a fluid, whereas solvents are substances that dissolve a solute to form a solution and are often hydrocarbons; both can be intoxicating.

Clinical Manifestations and Life-Threatening Complications

Oral Ingestion

Different routes of exposure result in distinct clinical toxicities (Fig. 5). When ingested, hydrocarbons are primarily gastric irritants that will cause

spontaneous vomiting in about 35% of patients [3]. Although rare, hemorrhagic gastritis can occur [4]. In the absence of aspiration, most exposures result only in gastrointestinal discomfort [5]. This was confirmed in an experimental canine model in which kerosene was injected directly into the stomachs of dogs who had previously undergone esophageal ligation [6]. The most concerning element of most oral hydrocarbon ingestions is the high risk of pulmonary aspiration and its associated complications.

Aspiration and pulmonary injury most often occur in children who attempt to ingest liquid hydrocarbons. However, similar injuries resulting from patients siphoning diesel [7] or “fire-eating” (an artistic performance of spraying liquid hydrocarbons by mouth over a flame) [8] have also been reported. Hydrocarbons cause pulmonary toxicity by disrupting the surfactants that line the distal bronchioles and alveoli. They do so by two mechanisms. First, they decrease the maximum surface tension of the surfactants, which limits the ability of surfactants to attract each other at higher external pressures. Second they increase the minimum required surface tension to initiate surfactant molecular aggregation. Because pulmonary surfactants line the alveoli and distal bronchioles, this surfactant disruption leads not only to alveolar instability and collapse but also to distal airway obstruction [9]. The end result is ventilation-perfusion mismatch, bronchospasm, shunt formation, and hypoxia. Aspiration of halogenated

hydrocarbons, such as trichloroethylene, causes mucosal irritation and can lead to caustic pneumonitis and acute lung injury [10].

Initial symptoms of aspiration are nonspecific and include cough, nausea/vomiting, drowsiness, fever, tachypnea, tachycardia, and occasionally altered mental status. In one series of patients with aspiration, fever was the most common sign, occurring in up to 94% of patients [11]. However, most studies indicate that fever is much less common. In another study of 274 children with hydrocarbon pneumonitis, only 64% had fever, 51% had vomiting, and 38% had cough [12]. When present, the fever resolves within 24 hours in 41% of patients, and only 6% have fever that lasts longer than 5 days [13]. Physical examinations are notoriously insensitive in identifying patients with complications from a hydrocarbon ingestion.

One specific form of pulmonary toxicity is the development of exogenous lipid pneumonia (ELP), a pulmonary disease that results from the inhalation or aspiration of animal, vegetable, or mineral oils. (Fig. 2) Most cases occur from chronic exposures to mixtures of inert, long-chain, saturated hydrocarbons derived from petroleum. According to one study of 44 cases, most chronic exposures were due to either ingestion of liquid paraffin for the treatment of constipation or inhalation of cutting mist or oily vapors by workers in metallurgic plants. Their mean exposure was for 9.5 years [14]. However, ELP has also occurred

Fig. 2 Exogenous lipid pneumonia: https://openi.nlm.nih.gov/detailedresult.php?img=2668105_CPT-62-05-0387-f22&req=4

after single, large intravenous injections of peppermint oil [15], olive oil [16], and lamp oil (liquid paraffin) [17]. Usual symptoms include cough and dyspnea; however, acute respiratory distress syndrome requiring mechanical ventilation has also been reported. Medical conditions that predispose to ELP include dysphagia, hypopharyngeal diverticulum, tracheoesophageal fistula, achalasia, and gastroesophageal reflux [18].

Inhalation

Most clinically significant hydrocarbon inhalation exposures occur as a result of intentional abuse and their ability to produce euphoria similar to that of ethanol inebriation. There are three main methods of inhalant abuse: sniffing is inhaling directly from the container that holds the hydrocarbon, huffing is inhaling from a cloth that was soaked in the hydrocarbon by holding it over the nose and mouth, and bagging is the breathing of vapors directly from a bag containing a hydrocarbon in order to maximize the concentration of inhaled fumes [19]. Gaseous hydrocarbons, such as refrigerants, propane, and inhalation anesthetics, are gases at room temperature and pressure but are compressed into liquids inside containers. When the container is opened and pressure released, these liquid hydrocarbons change phase into a gas and are released. Because the phase change from a liquid to a gas requires energy, ambient heat is absorbed resulting in decreased temperature surrounding the liquid. Thus, if the phase change occurs close to the skin, it can cause freeze burns. Nitrites, or “poppers,” consist of cyclohexyl nitrite, amyl nitrite, or butyl nitrite. Instead of causing direct central nervous system (CNS) intoxication, they relax smooth muscles and heighten sexual experiences [20].

Neurophysiologic effects of inhalants are poorly understood. There is evidence that they lead to CNS depression via gamma-aminobutyric acid (GABA) agonism, *N*-methyl-D-aspartic acid (NMDA) antagonism, inhibition of normal cell-cell signaling, and enhanced serotonergic transmission [21]. They also directly activate dopamine neurons in the ventral tegmental area, thus reinforcing their abuse [22]. Chronic abusers

develop tolerance to these effects and may increase the amount inhaled to compensate. They may acquire physical dependence and thus cessation of use results in a withdrawal that includes craving, irritability, and insomnia [23].

Inhalation of hydrocarbon vapors causes altered mental status and in high concentrations act like simple asphyxiants via displacement of oxygen. Symptoms of hydrocarbon intoxication generally consist of two main stages: the first involves euphoria, excitability, disinhibition, and impulsive behavior; the second stage is characterized by CNS depression with slurred speech, confusion, hallucinations, diplopia, tremors, ataxia, and weakness [24]. High frequency users are more likely to feel euphoria and grandiosity but also experience more depressed moods and suicidal ideation [25]. Chronic exposure to inhaled toluene, as described in one case of a 22-year-old male with daily toluene sniffing for 10 years, can lead to irreversible leukoencephalopathy and presents as cerebellar ataxia, parkinsonism, encephalopathy, convulsions, and/or deficits in higher functioning [26]. Neuroimaging in these patients reveals abnormalities in the cerebral cortex, cerebellum, hippocampus, basal ganglia, and brainstem [27].

Inhalation of volatile hydrocarbons, especially halogenated derivatives, can lead to cardiac arrest referred to as “sudden sniffing death.” This phenomenon was initially described in the 1960s by Bass as cardiac arrest following inhalation of volatile hydrocarbons in the presence of hypercapnia or stress [28]. It was suspected that halogenated hydrocarbons may sensitize the myocardium to catecholamines which predisposes to dysrhythmias. However, subsequent epidemiological studies have shown that death in these patients occurred due to other causes including plastic bag asphyxia, aspiration, upper airway occlusion, excessive CNS depression, and combustion burn injuries [29].

Dermal

Prolonged dermal exposure to hydrocarbons can lead to a defatting process which can cause partial or full thickness skin necrosis. Histologically this

manifests as disorganization of cells, cytolysis, and enlarged intracellular spaces in the stratum corneum and stratum spinosum cells of the epidermis [30]. Because hydrocarbons are sensitizers, in cases of repeated low concentration dermal exposures, they can cause allergic dermatitis, a form of delayed type IV hypersensitivity [31].

Unique Toxicities

Various hydrocarbons have unique toxicities some of which will be reviewed in the following section.

Hepatotoxicity

Hepatotoxicity and liver failure can occur following hydrocarbon exposure. Halogenated hydrocarbons are particularly hepatotoxic, whereas most other hydrocarbons induce only mild hepatic injury. Carbon tetrachloride is the prototypical example and is one of the most hepatotoxic substances known; it induces centrilobular liver necrosis via cytochrome 2E1 metabolism in a manner similar to the acetaminophen (paracetamol) induced hepatocellular damage [32, 33].

Renal Toxicity

Both halogenated and nonhalogenated hydrocarbons can cause acute renal failure primarily via tubular injury [34]. Toluene inhalation is notorious for inducing renal tubular acidosis, ureteral calculi, and acute renal failure [35, 36]. Acute toluene exposure presents with a widened anion gap acidosis due to the formation of the unmeasured anions, benzoate, and hippurate [37]. Chronic toluene exposure results in distal renal tubular acidosis, normal anion gap metabolic acidosis, and electrolyte abnormalities including hypokalemia, hyperchloremia, hypomagnesemia, and hypophosphatemia. Some patients present with life-threatening hypokalemia and resultant muscle weakness or paralysis [38].

Hematologic Toxicity

One hematologic pathology is hemolysis, and even though most cases are mild and self-limiting,

some are severe enough to require transfusion or exchange transfusion [39]. For example, naphthalene is a potent hemolytic agent found in certain mothballs that can also induce methemoglobinemia [40]. Other hydrocarbons, especially ones that contain nitrogenous side groups such as nitrites or “poppers” can also induce methemoglobinemia when ingested or inhaled [41, 42].

Carbon Monoxide Toxicity

Another hydrocarbon-induced pathology is carbon monoxide toxicity via methylene chloride exposure. Inhalation of methylene chloride from commercial paint remover is one source of this typically occupational injury [43]. After absorption, methylene chloride is slowly released from body tissues and metabolized to carbon monoxide potentially leading to carbon monoxide toxicity 1–6 hours post ingestion [44, 45]. This slow release and metabolism causes the carboxyhemoglobin concentrations to remain elevated for much longer than in inhaled carbon monoxide.

Diagnosis

Radiographic findings in patients with hydrocarbon pneumonitis are variable. In one retrospective study of 150 hospitalized children with hydrocarbon ingestion, 90% of patients with pulmonary symptoms on arrival to hospital had abnormal chest radiographs. However, 50% of patients with no pulmonary symptoms at the time of hospital evaluation had abnormal chest radiographs, and of those 5% developed symptoms during the next six hours of observation [5]. In another retrospective study of 205 children admitted with kerosene poisoning, 5% with positive radiological evidence of pneumonitis had no clinical signs or symptoms [11]. Interstitial lobar infiltrates are the most common finding, occurring in 94% of patients who develop a radiographic abnormality and most often involve middle and lower lobes. Other potential pulmonary abnormalities are pleural effusions, collapse, and pneumothorax [11] (Fig. 3).

Fig. 3 Examples of chest radiographs in patients with aspiration. (a) Chest radiograph showing bilateral alveolar consolidations after aspiration [50]. (b) CT image of the

thorax after aspiration [50]. (c) Relative distribution of bronchopneumonic changes after aspiration as observed per one pediatric study [11]

Definitive diagnosis of hydrocarbon pneumonitis requires demonstration of lipid-laden macrophages in bronchoalveolar lavage fluid in the presence of history consistent with hydrocarbon aspiration. On chest computer tomography, the most common findings are consolidation with air bronchograms, ground-glass attenuation, and

areas of low attenuation within the consolidations [18].

Exogenous lipid pneumonia is diagnosed when all of the following are present: (1) presence of abnormal chest radiograph, (2) presence of intrapulmonary lipids, proven by histological examination or bronchoalveolar

lavage, (3) presence of optically empty vacuoles, sometimes confirmed by a fat stain (Fig. 2), and (4) history consistent with hydrocarbon ingestion. Computer tomography of the chest usually reveals alveolar consolidation and ground-glass opacities [14].

Renal toxicity from chronic hydrocarbon exposure can lead to a slow decline in renal function via progressive tubular injury, and albuminuria is a useful marker in gauging the severity of injury [46]. In the presence of toluene ingestion, elevated urinary hippuric acid concentration is a useful diagnostic marker.

Treatment

Pulmonary Toxicity

Treatment of hydrocarbon pneumonitis is supportive. Most patients will have mild signs and symptoms, and those with reactive airways should be given beta-adrenergic agonists for the treatment for bronchospasm [47] (Level of Evidence [LoE] III). However, severely ill patients may require mechanical ventilation for respiratory support. In one case report, high frequency percussive ventilation (HFPV) resulted in a significant clinical improvement in a patient who deteriorated while on other modes of ventilation (LeE III). The authors of that case noted how the HFPV helped with mucous plugging by mobilizing large amounts of thick oily secretions [48]. Both extra corporeal membrane oxygenation (ECMO) [49] and surfactant therapy [50] have also been described in case reports and is an option for those with refractory hypoxia (LoE III).

Corticosteroid therapy in hydrocarbon pneumonitis was believed to reduce the inflammation and subsequent fibrosis and edema. However, because clinical effects and radiographic findings are often present 30 min after aspiration, it might be too late for this treatment to exert its anti-inflammatory action. In one randomized clinical trial of 71 mild to moderately ill patients, compared to placebo, corticosteroids did not decrease the number of days with abnormal temperature, respiratory rate, pulse, or hospital length of stay

[51] (LoE I). Thus, there is no established role for corticosteroid therapy in the treatment of hydrocarbon pneumonitis.

There is no demonstrated role for antibiotics in the treatment of hydrocarbon pneumonitis. Hydrocarbon aspiration predominantly results in a sterile inflammatory chemical pneumonitis [9]. The pneumonitis is usually mild and patients are typically able to go home within a few days. However, there is a theoretical concern for the lung's subsequent susceptibility to bacterial superinfection for which antibiotics might be helpful. However, in a double-blind randomized clinical trial of 200 children with mild pneumonitis after kerosene ingestion, antibiotics did not decrease hospital length of stay, improve treatment success, or improve clinical symptoms in patients [52] (LoE I). Therefore, based on the current state of knowledge, prophylactic antibiotics have no established role in the management of hydrocarbon aspiration.

Gastrointestinal Toxicity

Gastric lavage in patients with hydrocarbon ingestion is not recommended because of concern that re-exposing the patient's glottic opening to the substance increases the risk of pulmonary aspiration. This concern is supported by studies showing higher incidence and severity of aspiration pneumonia in patients who had undergone gastric emptying [53].

Treatment with *N*-acetylcysteine is hepatoprotective in animal models and in case reports of acute human exposure to hepatotoxic hydrocarbons [54, 55] (LoE III). While data are limited regarding the effectiveness of *N*-acetylcysteine in these exposures, we recommend that it be used because of its low cost and wide safety profile. A convenient dosing regimen is that which is used for acetaminophen poisoning. The clinical pharmacology of this agent can be found in ► Chap. 154, "*N*-Acetylcysteine".

Cardiotoxicity

Toluene causes electrocardiographic QT interval prolongation which can lead to dysrhythmias [56].

These arrhythmias can persist for days and are usually treated with beta-adrenoreceptor antagonists such as esmolol [57] (LoE III). Torsade de pointes (TdP) should be treated using standard protocols. Prevention strategies and the treatment of TdP are described in detail in Chap. 22, “Toxicant-Induced Torsade de Pointes”. The Volatile organic solvents sensitize the myocardium to catecholamines, and superimposed adrenergic stimulation, such as sudden excitation or exercise, can trigger ventricular dysrhythmias [58]. Beta-adrenergic blockers can blunt myocardial sensitization [59] (LoE III). Amiodarone and lidocaine have been used successfully to terminate ventricular arrhythmias [59] (LoE III).

Nephrotoxicity

Toluene is one of the hydrocarbons that is nephrotoxic. When renal toxicity develops, treatment is focused on hydration and repletion of electrolytes, primarily potassium. Sodium bicarbonate should be used with caution to treat acidosis as it can further decrease extracellular potassium thus worsening the existing hypokalemia-induced weakness/paralysis. Hemodialysis may be required to reverse severe hypokalemia [60] (LoE III).

Neurotoxicity

Treatment of acute inhalant induced intoxication is mostly supportive. In chronic users who develop signs or symptoms after cessation, there are no consensus recommendations for the treatment of the inhalant withdrawal syndrome. Baclofen, a GABA-B receptor agonist, was described in one case series of three patients as an effective treatment for symptom relief [61] (LoE III). Lamotrigine, an anticonvulsant that decreases the release of glutamate and aspartate, decreasing NMDA stimulation; a 5-HT₃ receptor antagonist; and a dopamine uptake inhibitor showed promising results in one case report of the treatment of inhalant dependence [62] (LoE III).

Dermal Toxicity

Dermal exposure typically results in mild irritant dermatitis that can be treated by cleansing the area with soap and water to remove residual hydrocarbons, followed by emollient application. Once damage to the skin develops, it can be treated similar to burn injury. If one develops allergic dermatitis, the treatment is primarily avoidance of future exposure.

Disposition

Figure 4 provides an algorithm for the disposition of patients following hydrocarbon exposures.

Special Populations

Pregnant Patients

Very little information exists linking acute toxic hydrocarbon ingestion with adverse maternal or fetal outcome. In one case report of an acute gasoline ingestion, a 38-week pregnant female developed transient respiratory distress with fetal heart rate decelerations prompting emergent cesarean delivery. Both the mother and baby did well at discharge 15 days later [63]. The appropriate treatment approach, based on the current state of knowledge, is to treat the mother as needed in the hope that this will serve to treat the fetus.

Key Points

Hydrocarbons are ubiquitous in the outdoor and indoor environments.

Most exposures are benign; however, some may require ICU observation and treatment.

Significant exposure can affect multiple organs (i.e., central nervous system, cardiac, gastrointestinal, dermal, and respiratory).

(continued)

Disposition Algorithm:

Fig. 4 Disposition algorithm

Fig. 5 Clinical effects of hydrocarbons

Pulmonary Bronchospasm Pneumomediastinum Pneumatocele Chemical pneumonitis Pneumonia Pleural effusions ARDS	Gastrointestinal Abdominal pain Nausea/Vomiting Hepatitis/Liver failure
Cardiac Arrhythmias Myocardial infarction	Renal Type I RTA Ureteral calculi Glomerulonephritis Actue tubular necrosis Acute renal failure
Neurologic CNS depression Euphoria Peripheral neuropathy Psychiatric disorders Seizures	Dermatology Allergic dermatitis Chemical burn
	Other Hemolysis Methemoglobinemia Cancers

All suspected hydrocarbon ingestions should receive a chest radiograph and be observed for at least 6 hours.

Place all symptomatic patients on cardiac monitor.

- Common Errors**
- Not recognizing hydrocarbon components of ingestion.
 - Medically clearing patients prior to completing 6 hours of observation.

(continued)

- Not recognizing subtle symptoms of toxicity during observation which should prompt automatic admission.

Criteria for ICU Admission

- Respiratory distress/failure
- Hemodynamic instability
- Altered mental status or seizures
- Presence of arrhythmias or cardiac dysfunction
- Extensive chemical burn

Criteria for ICU Discharge

- Off respiratory and hemodynamic support
- Improving mental status

Hydrogen sulfide (H₂S), cyanide, azide, and carbon monoxide are collectively referred to as *cellular asphyxiants* or *chemical asphyxiants* because of their ability to disrupt aerobic cellular respiration. Exposure to H₂S is associated with a “knockdown” effect and may be rapidly fatal. The American Association of Poison Control Centers reported 766 H₂S exposures in 2013, with 327 treated in a healthcare facility and 10 deaths [1]. Hydrogen sulfide is the second most common cause of fatal gas inhalation in the workplace [2]. Olfactory fatigue to the smell of H₂S occurs quickly and has led to fatal poisoning of rescuers on multiple occasions [3, 4].

Hydrogen sulfide is known as “sewer gas” and is naturally produced by the putrefaction of organic substances such as sewage, manure, offal, and fish in ships’ holding tanks. Decomposition of sulfur-containing proteins by bacteria produces H₂S. Hydrogen sulfide gas can therefore be anticipated whenever organic material containing sulfur is in an anaerobic environment.

Major industrial uses for H₂S include production of elemental sulfur, inorganic sulfides, and sulfuric acid. Hydrogen sulfide is also found as an additive in high-pressure lubricants and cutting oils. Hydrogen sulfide is a commonly encountered toxin in several industries including paper making, leather tanning, and most notably, oil and natural gas production. “Sour gas” refers specifically to natural gas that contains significant quantities of hydrogen sulfide; H₂S must be removed from the gas prior to its use as fuel [5].

Table 1 Selected natural and industrial sources of hydrogen sulfide

Natural gas wells	Sewers/waste water treatment
Oil wells	Manure pits
Sulfuric acid production	Fish in ship holds
Coke ovens	Undersea vents
Tanneries	Volcanos
Iron smelting	Tar and Asphalt manufacturing
Rayon production	Food processing plants
Kraft paper mills	Chemical refineries

Hydrogen sulfide is also naturally produced and liberated from volcanos and undersea vents. One example occurs in the Puna District on the island of Hawaii, where an active volcano emits H_2S , typically in concentrations of less than 20 parts per billion (ppb) [6]. A similar volcanic off-gassing site exists in the City of Rotorua on the north island of New Zealand [7] (Table 1).

In 2007, the first case of “detergent suicide” was reported in Japan. This method of suicide involves mixing a commercially available, sulfur-containing product with an acidic toilet bowl cleaner to produce hydrogen sulfide gas. Instructions and ingredient lists were published and rapidly popularized through internet message boards. By 2008, an epidemic of detergent suicides was underway in Japan, with nationwide deaths due to hydrogen sulfide poisoning increasing from 27 in 2007 to 1,027 in 2008 [8]. In the United States, hydrogen sulfide suicides increased from 2 in 2008, to 10 in 2009, and 18 in 2010 [9]. Detergent suicides have caused evacuation of commercial and residential buildings; fatalities among family members with secondary exposure have also been reported [8, 10].

Biochemistry and Clinical Pharmacology

Hydrogen sulfide is normally present in small amounts in the human body. As a component of intestinal gas, H_2S has been found in concentrations of 1–4 ppm with some high levels of 18 ppm [11]. Hydrogen sulfide is synthesized in small

amounts in neuronal cells and within the cardiovascular system, in addition to being released from intracellular sulfur stores. Recent studies demonstrate many physiological effects of endogenous H_2S , and it has been proposed as the third gasotransmitter, a family of small molecules that participate in cell signaling via diffusion across cell membranes [12].

Hydrogen sulfide appears to be an important vasoactive agent similar to nitric oxide. It has been reported to have an inotropic effect and alter the growth of vascular endothelial cells [13]. There is also a link between H_2S and insulin release [14]. In the CNS, there appear to be physiological roles in GABA and NMDA transmission [15]. Hydrogen sulfide can reduce reactive oxygen species both directly and via increasing glutathione production, protecting neuronal cells from death [16]. Hydrogen sulfide is currently being investigated for neuroprotective, cardioprotective, antioxidant, and anti-inflammatory effects, with several experimental H_2S -donating drugs under study [12]. At higher doses, however, predictable toxic effects of H_2S occur that are discussed in detail below.

Hydrogen sulfide is a colorless gas, slightly heavier than air, with a relative vapor density of 1.19, and is slightly less volatile than water at room temperature. It has a molecular weight of 34.08 g/mol. Hydrogen sulfide has a water solubility (3.2 g/L at 30 °C) between ammonia, which is highly soluble, and chlorine, which has low solubility. Its metabolism is rapid; no bioaccumulation occurs [11]. H_2S smells like rotten eggs. However, olfactory fatigue and the loss of the ability to smell H_2S can occur in seconds. The odor threshold is reported in the range of 1–130 ppb, with olfactory fatigue occurring around 100 ppm [17].

The principle pathway of exposure is via inhalation. It has minimal absorption through the gastrointestinal tract and intact skin. Hydrogen sulfide is highly lipid soluble and rapidly diffuses across cellular membranes. Following human exposure, distribution to tissues is rapid [18].

Hydrogen sulfide is metabolized by three major pathways. The primary metabolic

elimination pathway is via oxidation of sulfide to thiosulfate, which is converted into sulfate, ultimately being excreted in the urine [19]. Hydrogen sulfide is also metabolized by methylation and reactions with metalloproteins or disulfide-containing proteins. Though in vitro studies demonstrated H₂S-induced sulfhemoglobinemia, recent evidence suggests that clinically significant sulfhemoglobinemia does not occur in acute hydrogen sulfide poisoning [20].

Pathophysiology of Toxic Effects

Hydrogen sulfide causes cellular anoxia by the inhibition of mitochondrial cytochrome *c* oxidase. This inhibition results in disruption of the electron transport chain, impairing oxidative metabolism and the resultant production of ATP. Tissues with high metabolic demands (e.g., brain and heart) are therefore especially susceptible [11].

Hydrogen sulfide also may reduce disulfide bridges in proteins, which is thought to be the mechanism of its inhibition of succinate dehydrogenase. Because of its water solubility, H₂S has irritant effects on moist mucous membranes but also may result in distal airway injury if a high respiratory rate is maintained while exposed. Minimal H₂S is excreted via the lungs.

Hydrogen sulfide directly stimulates carotid arterial chemoreceptors, causing an increased respiratory rate. Noncardiogenic pulmonary edema may develop prior to respiratory arrest. Terminal respiratory depression likely results from H₂S being selectively taken up by respiratory center of the brainstem with an end point similar to anoxia. The underlying mechanism is thought to be inhibition of monoamine oxidase [21, 22].

Clinical Presentation and Life-Threatening Complications

Two common adverse effects occur after H₂S poisoning: mucous membrane irritation and systemic toxicity. These occur in a dose-response fashion (Table 2). Hydrogen sulfide reacts with

Table 2 Range of toxicity of hydrogen sulfide (Adapted from references [11, 23, 24])

Clinical effect	Concentration (ppm)
Eye irritation	20–100
Olfactory fatigue	100
Respiratory irritation, possible pulmonary edema	50–500
Symptomatic	50 for 0.5 h
Severely toxic	200 for 1 min
Bronchitis, noncardiogenic pulmonary edema	250 for 24–72 h
Coma and death	500–1,000
Fatal	800 – immediate; 600 – 30 min
Immediate collapse	700–1,000

water to form irritating acid sulfides. Mucous membranes are especially susceptible to the effects of H₂S because of their moisture and anatomic proximity to the environment. The irritant effects of H₂S to the face are sensed by the trigeminal nerve and the olfactory nerve detects its odor, although there may be significant overlap between these two domains.

Membrane irritation begins to occur with H₂S exposures in the range of 2–5 ppm. Mild nausea, vomiting, and lacrimation tend to occur in the range of 80–100 ppm. Higher concentrations, in the range of 500 ppm, typically are required to cause immediate respiratory symptoms. Obvious signs of systemic toxicity tend not to occur until H₂S concentrations of approximately 250 ppm have been attained. Findings at these concentrations may include cough, tachypnea, chest pain, headache, dizziness, lethargy, and confusion. At still higher concentrations, seizures and coma occur. Concentrations of 1,000 to 3,000 ppm were fatal to dogs; death occurred within 15–20 min at 1,000 ppm. At the higher concentration, respiration ceased after a few breaths [21]. The most common clinical findings after H₂S exposures are headache, nausea, vomiting, dyspnea, disequilibrium, conjunctivitis, sore throat, and unconsciousness [25]. A toxidrome for hydrogen sulfide poisoning has been proposed by Guidotti, consisting of any one or combination of the following effects:

- Odor perception (followed by olfactory paralysis)
- Conjunctivitis
- Pulmonary edema
- Acute central neurotoxicity (“knockdown”) [2].

Ocular Effects

The eyes react first to the irritant effects of H_2S . As levels increase, the conjunctivae may become inflamed and swollen. After major exposures, the cornea may develop erosions and ulcerations. Associated signs and symptoms include photophobia, lacrimation, and pain. Because both the cornea and the conjunctivae are affected, the term *keratoconjunctivitis* is used to describe the eye effects. This is known in industry as “gas eye.” Visual impairment lasting for days has been reported. The possibility of permanent blindness after hydrogen sulfide exposure remains controversial [26].

Knockdown Effects

Hydrogen sulfide is known for its rapid “knock-down” capability. At ambient concentrations of 700–1,000 ppm H_2S , exposed persons may suddenly collapse. If the exposure is terminated promptly, this situation may result in no residual effects [27]. Frequently, workers in the oil fields report this effect; after recovering, they resume their work [5]. If exposure is not terminated, respiratory arrest may occur rapidly.

Pulmonary Effects

Inhaled irritants tend to increase the respiratory rate and decrease the minute volume. Hydrogen sulfide directly produces an increase in ventilation mediated by carotid arterial chemoreceptors at doses below those sufficient to cause central apnea [28]. Significant H_2S exposure may result in redness, inflammation, sloughing, or exfoliation of the airways as H_2S reacts with the moisture of the mucosal surfaces. Hemorrhagic bronchitis

has been reported and may require ventilatory support [29].

Due to the moderate water solubility of H_2S , the gas can penetrate the deep airways of the lung and injure alveoli, causing pulmonary edema. The prevalence of pulmonary edema in H_2S -poisoned patients reaching the emergency department has been reported from 4% to 20% [2, 27]. Pulmonary edema appears to make a small contribution to mortality in H_2S poisoning, presumably because respiratory arrest occurs so rapidly in those severely poisoned. Cases of interstitial pulmonary fibrosis following hydrogen sulfide poisoning have also been reported, but appear to be exceptionally rare [30].

Cardiovascular Effects

Typical and atypical chest pain, dysrhythmias, and acute myocardial infarction with heart failure are reported after H_2S exposure [31]. Cardiovascular effects are most likely due to cellular anoxia, rather than direct toxic effects of H_2S on cardiac myocytes. In fact, recent literature describes *protective* effects of low levels of H_2S against myocardial ischemia/reperfusion injury, infarction, and cardiac dysrhythmias in animal and in vitro models [32, 33].

Neurologic Effects

Early-onset neurologic symptoms (dizziness, ataxia, headache, “knockdown”) are believed to be due to direct toxic effects of hydrogen sulfide. Coma, seizures, or signs of increased intracranial pressure from edema may occur in the setting of cerebral anoxia. Those who survive acute exposures to high levels of H_2S frequently make a complete neurologic recovery. However, some H_2S poisonings with loss of consciousness have been associated with long-term neurological dysfunction, including headaches, memory problems, motor dysfunction, and neuropsychiatric effects [24]. These are proposed to result from secondary anoxic brain injury caused by respiratory arrest, seizures, or other hypoxia resulting from H_2S

poisoning (i.e., pulmonary edema) [2]. Trauma may also accompany acute H₂S exposures due to knockdown effects, confounding the causality assessment of neurological sequelae [34, 35]. Although acute high-level exposures may result in altered neurological function, quality evidence that chronic low-level exposures cause long-term harm is lacking.

Metabolic Acidosis

Metabolic acidosis, with elevated lactate concentration, may occur in individuals with serious H₂S poisoning due to impairment of oxidative phosphorylation, ATP consumption exceeding production, and the resulting shift to anaerobic metabolism.

Death

Twenty-nine deaths from 5,563 H₂S exposures in the United States were reported to the American Association of Poison Control Centers over a 9-year period [23]. Most fatal cases involved exposures occurring in confined spaces, such as sewers, animal-handling and processing plants, waste dumps, sludge plants, tanks and cesspools, pulp mills, and other confined environments. In case reports of deaths occurring after acute H₂S exposure, individuals lost consciousness after only one or two breaths; this is known as the “slaughterhouse sledgehammer” effect [23, 36–39]. In these fatal cases, patients seemed to succumb from respiratory failure, acute pulmonary edema, or coma. Patients exposed to only H₂S gas do not have a substantial risk of secondary contamination to personnel outside the so-called hot zone. Rescuers should be trained and attired properly with positive-pressure, self-contained breathing apparatus before entering the hot zone.

Diagnosis

The exposure history and clinical presentation are the keys to making the diagnosis of acute hydrogen sulfide poisoning. A rotten egg odor on a

patient or their belongings is suggestive of H₂S, though other agents have a similar smell, including sulfur compounds such as mercaptans, carbon disulfide, and trimethylamine. Historically, dark discoloration of a patient’s coins and jewelry has been suggested as a clue to H₂S poisoning.

Important toxicologic differential diagnoses with presentation similar to H₂S poisoning include other cellular asphyxiants, such as carbon monoxide, cyanide, azide, and cyanide-related substances.

The presence of metabolic acidosis can be further evaluated by assessment of arterial blood gases with co-oximetry, electrolytes, and lactate concentrations. If the diagnosis of H₂S poisoning is not immediately obvious, cyanide, toxic alcohols (ethylene glycol, methanol), salicylate, and carboxyhemoglobin concentrations should be obtained, if indicated by the clinical history.

Sulfide ion levels can be measured on whole blood. However, lack of specificity, difficulty in performing the test accurately, and limited availability make sulfide levels useless in initial diagnosis [18]. One case series found urine thiosulfate concentrations elevated in nonfatal H₂S poisoning, despite undetectable blood sulfide levels. Urine thiosulfate may therefore be a useful means of confirming H₂S poisoning in patients who survive exposure [40]. Industrial hygienists, hazardous materials responders, and firefighters can measure H₂S concentrations in the ambient atmosphere around the site of an incident. In the case of an identified H₂S release or exposure, it is critical that H₂S concentrations are directly communicated with the individuals on site, so that appropriate precautions can be taken and secondary casualties prevented.

Treatment

Supportive care is the mainstay of therapy for exposures to H₂S. This includes removal from exposure, administration of supplemental oxygen, and decontamination of the eyes and skin. Decontamination can be accomplished by copiously irrigating exposed skin and eyes with normal saline or water. Ventilatory support, administration of

anticonvulsants if there is seizure activity, intravenous fluids, and vasopressors may be necessary. Cycloplegics and antibiotics may be needed for eye injuries. Systemic antibiotics may be indicated if there is evidence of superinfected aspirated pulmonary secretions.

Indications for ICU Admission in Hydrogen Sulfide Poisoning

Respiratory distress, respiratory failure, or signs of airway injury
Unconsciousness
Seizures or persistent neurological impairment
Electrocardiogram changes

Methemoglobin Induction

One possible antidotal therapy is induction of methemoglobinemia. Hydrogen sulfide poisoning causes lactic acidosis by the inhibition of cytochrome *c* oxidase and depletion of ATP. The formation of methemoglobinemia by nitrites creates a large pool of ferric iron, which has a greater affinity than cytochrome *c* oxidase for H₂S. Methemoglobin may therefore serve as a sink, allowing cytochrome *c* to be reactivated and reestablishing aerobic metabolism [41–43]. However, the period during which H₂S is available in blood after removal from exposure is short-lived. One animal model found no benefit to infusion of a methemoglobin solution 90 s after termination of a toxic H₂S exposure [44]. Future research is needed to determine if antidotes that propose to work by binding diffusible H₂S, including methemoglobin induction, are truly effective.

One method of inducing methemoglobinemia is by use of sodium nitrite, which may be found as a component of a cyanide antidote kit. The use of nitrites in H₂S poisoning is supported by animal studies and human case reports (Grade III evidence) [45, 46]. Intravenous (IV) access should be established as soon as possible and IV sodium nitrite administered once the decision is made to induce methemoglobinemia. The generally accepted adult dose of sodium nitrite is 10 mL of a 3% solution; the pediatric dose is 0.33 mL/kg up to 10 mL but may be adjusted based on

hemoglobin level. Because sodium nitrite is a potent vasodilator, it should not be administered rapidly, but given over 2–5 min. The thiosulfate portion of the cyanide antidote kit is not useful in H₂S poisoning. Sulfide is present in the blood only transiently, and methemoglobin therapy is *not* indicated in most patients. If a patient has persistent acidosis, shock, cardiotoxicity, or coma despite optimal supportive care, the authors recommend induction of methemoglobinemia given the above animal and case-based human evidence supporting possible benefit.

Hydroxocobalamin and Cobinamide

Hydroxocobalamin, a precursor of Vitamin B₁₂, and cobinamide, a Vitamin B₁₂ analog, both have a high affinity for sulfides and have been investigated as possible antidotes for H₂S poisoning. Animal models suggest a reduction in lethality and amelioration of cardiac depression with hydroxocobalamin treatment [47, 48]. A single fatal human case report notes a reduction in blood sulfide levels after hydroxocobalamin treatment [49]. One rabbit model shows increased survival and binding of sulfide to cobinamide [50]. However, in these animal models, sulfide is continuously infused, generating a constant supply of H₂S that may complex with an antidote before entering cells. Neither hydroxocobalamin nor cobinamide has yet proven clinically useful in human H₂S poisoning. Again, this may be due to the extreme rapidity with which free hydrogen sulfide leaves the circulation and enters tissues, once victims are removed from exposure. Any complex-forming antidote that cannot be administered almost immediately is likely to be of limited value [51–53]. Given the current absence of evidence supporting antidotal effects of hydroxocobalamin and cobinamide in humans, the authors recommend against their use in hydrogen sulfide poisoning (Grade III Evidence).

Hyperbaric Oxygen

Hyperbaric oxygen is a theoretical therapy for H₂S poisoning. A few case reports and

retrospective series have described using hyperbaric oxygen for H₂S poisoning. In these cases, positive outcomes were reported (Grade III Evidence) [54, 55]. However, these data are uncontrolled and subject to publication bias. The pillar of evidence-based treatment for human hydrogen sulfide poisoning remains supportive care, once the patient has been removed from the source of exposure. Hyperbaric oxygen therapy is rarely immediately available and logistically often interferes with the provision of supportive care. It is therefore the authors' opinion that hyperbaric oxygen should not be used in human H₂S poisoning. Current evidence that does not demonstrate a clear benefit and there is a high likelihood that hyperbaric oxygen treatment will delay other beneficial aspects of care.

Prehospital Treatment

A study of 250 cases of exposure to H₂S in the Alberta oil fields found that with increased awareness and improved prehospital treatment, the fatality rate was reduced from 6% to 2.8%, unconsciousness on hospital arrival decreased from 13% to 2%, and hospital admission rates decreased from 51% to 22%. Prehospital treatment also resulted in an overall decrease in workers' compensation claims [34].

Prevention

Safety officers, industrial hygienists, and workers in those industries should learn the hazards of H₂S and the proper response in the event of an accident. Safe evacuation and prompt medical attention are important. Real-time gas detecting devices are available and should be used to monitor levels of H₂S before entry into a potentially contaminated zone.

Common Errors in Hydrogen Sulfide Poisoning

Failure to consider hydrogen sulfide in cases of rapid knockdown, multiple victim poisonings

at a single site, or unexplained poisoning in a confined space

Failure to account for olfactory fatigue to hydrogen sulfide gas

Failure to protect emergency personnel during attempted rescue of poisoned patients

Failure to consider hydrogen sulfide in cases of seizure, coma, or metabolic acidosis

Failure to assess for trauma secondary to sudden unconsciousness

Failure to treat on the basis of clinical presentation rather than reported or suspected exposure

Failure to perform ocular decontamination

Evidence-Based Recommendations for Practice

Clinical Recommendation	Evidence rating
Supportive care should include decontamination and oxygen supplementation	III
Methemoglobin induction with sodium nitrite may be considered for severely poisoned patients that remain symptomatic in medical care	III
Patients severely poisoned by H ₂ S should be evaluated for concomitant trauma	III

Key Points in Hydrogen Sulfide Poisoning

1. Hydrogen sulfide causes a rapid knock-down effect.
2. Decontamination is essential.
3. Safe removal from exposure and supportive care is the mainstay of therapy.
4. Trauma frequently accompanies H₂S poisoning and must be evaluated and treated.
5. Induction of methemoglobinemia with IV sodium nitrite may be antidotal.
6. Vitamin B₁₂ and its analogs currently lack human evidence for effectiveness.
7. Hyperbaric oxygen therapy currently lacks human evidence for effectiveness.

Toxic and irritating gases have been known to produce fatalities since the Athenians used a combination of pitch and sulfur to produce toxic fumes in a war against the Spartans in 428 BC. More sophisticated irritant agents were introduced during World War I, when mustard gas, chlorine, and phosgene were the primary agents of chemical warfare. These gases produced many incapacitating casualties but relatively few fatalities compared with conventional weapons. The use of mustard gas was reported in the 1988 war between Iraq and Iran, and more recently gas warfare was reported between Iraq and the Kurds.

Large amounts of irritant gases are produced; more than 0.5 million workers are exposed to anhydrous ammonia alone in the United States. In 1984, a disastrous release of large amounts of methyl isocyanate in Bhopal, India, resulted in approximately 2,500–5,000 deaths and 200,000 individuals with respiratory, eye, and other symptoms [1]. Smaller numbers are exposed to a variety of other irritant gases that are used in a multitude of industrial processes. In addition, many millions of people worldwide also are exposed to compounds related to the burning of materials that may generate toxic gases. This exposure most commonly occurs in commercial or home fires, where large amounts of hydrogen cyanide, hydrogen chloride, acrolein, sulfur dioxide, phosgene, and other irritant gases are produced (Table 1). Statistically, the major lethal gas still is the asphyxiant gas carbon monoxide.

The magnitude of the problem is significant. In 2014, over 133,000 inhalational exposures were reported to poison control centers [2]. Approximately 40% of 26,932 exposures annually involve an inhalational agent in the workplace [2]. Fumes, gases, and vapors are common causes of environmental exposures and constitute the largest mortality. Carbon monoxide, hydrogen sulfide, and hydrofluoric acid are the leading cause of death in the occupationally exposed group. The United States Department of Labor, the Bureau of Labor Statistics reports an average of greater than 11,000

Table 1 Common pyrolysis products of combustion

Substance	Toxic product
Acrylics	Acrolein
Batteries, paints	Metals (lead, zinc, manganese, cadmium, cobalt)
Coal, fuel, wood	Carbon monoxide
Fuels, fabrics, celluloid, nitrocellulose film	Oxides of nitrogen, cyanide, aldehydes
Fluorinated resins	Hydrogen fluoride
Melamine, silk, wool, polyurethane, nylon	Ammonia, hydrocyanic acid, hydrogen sulfide, isocyanates
Polyvinyl chloride	Chlorine, phosgene, hydrochloric acid
Rubber	Hydrogen sulfide, sulfur dioxide
Sulfur compounds	Sulfur dioxide
Wood, house fires, building fires	Acrolein, acetaldehyde, hydrocyanic acid, carbon monoxide, nitrogen dioxide, ammonia

nonfatal injuries and illnesses caused by inhalational exposure to harmful substances [3]. Inhalational exposure accounts for more than 58% of harmful substance-related deaths in the workplace [4]. Worldwide, the World Health Organization estimates two million premature deaths per year due to air pollution. Eighty-eight percent of those deaths occurred in low- and middle-income countries [5].

Biochemistry and Clinical Pharmacology

Exposure to toxic concentrations of inhalational agents may result in systemic injury and local injury to the respiratory system. Vapors and gases can be classified into several different types based on the physical state of the particular substance.

Dusts are a particular form of a solid organic or inorganic material that is small enough to be airborne. They usually are characterized by particles ranging from 0.1 to 25 μm in diameter.

Characteristics of Gases and Vapors

1. A gas is a state of matter in which the molecules move freely, allowing infinite expansion.
2. A vapor is a gas below its critical temperature at which it may be liquefied by an increased pressure.
3. The density of a gas is relative to air; the more dense a gas, the more likely it will seek low areas.
4. Cold gases are denser and seek low areas. Nitrogen acts as an asphyxiant in low areas when cold.

Fumes are extremely fine solid particulates that usually are formed by combustion or condensation of metals so that these metals have entered a gaseous state. Fumes usually range from 0.001 to 1.0 μm in diameter.

A *gas* is a substance that at standard conditions has a physical state in which molecules move freely, allowing infinite expansion. The vapor density of a gas by convention is expressed relative to air, which by definition has a vapor density of 1. The more dense (or the heavier) the gas, the more likely it will seek low areas in the air column. Decreased temperature increases the density of a gas. Nitrogen may act as an asphyxiant in low areas when cold. A gas is not capable of being liquefied by pressure alone and is liquefied by lowering its temperature and increasing pressure.

A *vapor* is a gas below its critical temperature at which it may be liquefied by an increased pressure alone. It may exist as either a liquid or a solid when it is in equilibrium with its vapor. So-called industrial gases – chlorine, ammonia, propane, and butane – are actually vapors.

A *fog* is a liquid aerosol formed by condensation from a gaseous to a liquid state.

Smoke is a mixture of airborne particles, vapors, and gases, resulting from the incomplete combustion of organic materials. These particles are usually less than 0.5 μm in diameter.

This chapter discusses primarily the health effects of gases, vapors, and fumes. A general

classification of toxic inhalants is presented in Table 2. Table 3 lists the common chemical exposures and their effects and the concentrations commonly associated with a significant health hazard. Although not irritants, asphyxiants are included for completeness (Table 4).

Irritant gases are gases that cause respiratory tissue injury by direct contact due to their chemical reactivity. Acid and alkaline gases, such as chlorine and ammonia, may produce extreme alterations in pH, and other gases may cause chemical reactions with membrane damage and release of free radicals. The site of the pulmonary injury is related largely to the water solubility of the various gases (Table 5). The various factors influencing the likelihood and degree of pulmonary injury are presented in Table 6.

Toxicokinetics

Inhalant gas toxicology is complex. The dose of an inhaled gas or vapor usually is expressed as the mass of the gas per unit volume, or milligrams per liter, or as the ratio of molecules of the study gas to total gas molecules; this usually is expressed as parts per million (ppm). The dose of an inhaled gas is calculated by multiplying the concentration of the gas in the breathing zone by the duration of the exposure and the minute ventilation of the individual during that exposure time:

$$\begin{aligned} &\text{Dose of an inhaled gas} \\ &= C (\text{concentration in the breathing zone}) \\ &\quad \times \text{minute ventilation} \end{aligned} \quad (1)$$

Dose-effect relationships may be expressed by Harber's rule: [6]

$$\begin{aligned} &C \times T (\text{time of exposure}) \\ &= K (\text{biologic effect}) \end{aligned} \quad (2)$$

Limitations of Harber's rule include the failure to take into account the minute ventilation or

Table 2 General classification of acute inhalational toxicants

I. Respiratory toxicants
A. Single agents
1. Asphyxiants
a. Simple
i. Carbon dioxide
ii. Methane
iii. Nitrogen
b. Chemical
i. Agents that decrease oxygen-carrying capacity
(a) Carbon monoxide
(b) Hydrogen sulfide
(c) Oxides of nitrogen
ii. Agents that inhibit tissue oxygen utilization
(a) Acrylonitrile
(b) Hydrogen cyanide
(c) Hydrogen sulfide
2. Irritants
a. High-solubility gases
i. Ammonia
ii. Methyl isocyanate
iii. Sulfur dioxide
b. Intermediate-solubility gases
i. Chlorine
c. Low-solubility gases
i. Hydrogen sulfide
ii. Oxides of nitrogen
iii. Phosgene
B. Mixtures
1. Smoke inhalation from fires
2. Smoke inhalation from smoke bombs
C. Illicit drug abuse
1. Airway burns from freebasing cocaine
2. Asphyxia from glue sniffing and organic solvent abuse
3. Drug-induced pulmonary edema
4. Pulmonary hypertension, pulmonary fibrosis, bullous emphysema secondary to intravenous drug abuse
D. War gases
1. Lethal agents (CG, DP, CL, PS, AC)
2. Riot control agents (CN, CS, CR, DM)
II. Systemic toxicants
A. Fluorinated polymers (polymer fume fever)
B. Metal oxides (metal fume fever)
C. Organic dusts (organic toxic dust syndrome)
D. Poisons (arsine, stibine, carbon tetrachloride)

Adapted from Ref. [149]

CG phosgene, DP diphosgene, CL phosgene, PS chloropicrin, AC hydrogen cyanide, CN 1-chloroacetophenone, CS *o*-chlorobenzylidene malononitrile, CR debenz (b,f)-1:4-oxazepine, DM diphenylaminearsine

tidal volume, which greatly affects the dose of inhalant reaching the alveoli. Harber's rule fails to recognize the exponential impact of increasing dose. With higher concentrations, the effect of concentration is far greater than the duration of exposure. In low concentration, the toxic effects are related primarily to duration of exposure, but only one or two breaths of a highly toxic concentrated irritant gas may be fatal. A more useful formula has been proposed by Baxter: [7]

$$\text{Toxic load} = \frac{\text{concentration to the exponent } n}{\times \text{time}} \quad (3)$$

The exponent n is any number other than 0. This reflects an exponential increase in tissue damage with increasing dose, which varies in amount with the physical properties of that gas. In some gases, the relationship is nearly linear, whereas in other exposures, such as hydrogen sulfide, the toxic effects increase in an exponential fashion so that only a few breaths in high concentration may be fatal. The primary determinant of toxicity with hydrogen sulfide is concentration rather than duration of exposure, invalidating Harber's rule [8].

In actuality, the estimate of exposure is much more complex than dose, duration of exposure, and chemical properties of a given gas. It is difficult to estimate the minute ventilation in an accidental exposure. The amount of gas going to the lower airways varies tremendously depending on whether the subject is breathing through the mouth or through the nose. Highly reactive gases, such as formaldehyde, would be taken up almost entirely in the nose if the patient were breathing through the nose, but some would get into the lower airways if the patient were breathing through the mouth. The distribution of the gas when it reaches the lower airways tends to be irregular if it is irritating to the bronchial mucosa. Studies in dogs by Winternitz [9] at the Department of Pathology at Yale during World War I showed severe congestion in some areas of the lungs with normal areas of the lung elsewhere, indicating irregular uptake of toxic war gases. It is believed that this irregular uptake

Table 3 Commonly used toxic gases and fumes and their dangerous levels of exposure

Agent	Principal occupations exposed	Time-weighted main mechanism of injury	Average ^a	IDLH level ^b
Acetic acid	Production of cellulose, dyeing, pharmaceuticals, food processing	Severe irritation of eyes, mucous membranes, skin; RADS, bronchitis, pneumonitis	10 ppm	500 ppm
Acrolein	Plastic, rubber, textile, resin making	Direct action on mucosa of the eyes and respiratory tract, irritant effects	0.1 ppm	5 ppm
Acrylonitrile	Synthetic fiber, acrylic resin, rubber making	Asphyxiant, neurotoxicity	2 ppm	4 ppm
Ammonia	Fertilizer, refrigerator, explosive production	Direct action on mucosa of the eyes and respiratory tract; tracheitis and pulmonary edema	25 ppm	500 ppm
Antimony trichloride or pentachloride	Metallurgy	Mucous membrane irritant, eye, skin, and lung; pulmonary edema	0.5 mg/m ³	—
Arsine	Smelting, refining, electronics	Systemic effects, hemolysis	0.05 ppm	6 ppm
Boron trifluoride	Fumigant, flux, catalyst	Irritant to eyes, skin, lungs; abnormal lung function	1 ppm	500 ppm
Cadmium oxide fumes	Ore smelting, alloying, welding	Tracheobronchitis, pulmonary edema, emphysema, renal effects	0.1 mg/m ³ (40 µg/m ³)	40 mg/m ³
Carbon dioxide	Foundry work, mining	Asphyxiant	10,000 ppm	50,000 ppm
Carbon disulfide	Degreasing, electroplating, sulfur processing, insecticide	Systemic effects, cardiac disease	10 ppm (1 ppm)	500 ppm
Carbon monoxide	Foundry work, petroleum refining, mining	Asphyxiant	50 ppm	1,500 ppm
Chloramine	By-product of mixture of bleach and ammonia-containing products	Common cause of pulmonary edema and pulmonary irritation in homemakers, custodians, and industrial workers	—	—
Chlorine	Bleaching, disinfectant, plastic making	Direct action on mucosa of the eyes and respiratory tract; tracheitis and pulmonary edema. Possible chronic effect and airways obstruction	0.5 ppm	100 ppm
Chloropicrin	Manufacture of pesticides	Irritation of eyes, mucous membranes, skin; pulmonary edema	0.1 ppm	100 ppm
Chromates	Electroplating	Cutaneous ulcers, dermatitis, nasal perforation, rhinitis, nose bleeds, laryngitis, tracheobronchitis, chemical pneumonitis, gingivitis, lung cancer	50 µg Cr (VI) 500 µg Cr (III)	100 mg/m ³ 100 mg/m ³
Chromyl chloride	Dye making, manufacturing chromium complexes	Severe irritant; second- and third-degree burns; eye, nose, throat, airway injury	0.025 ppm	1 ppm
Copper fumes	Welding	Systemic effects, “brass chills”	0.1 mg/m ³	—
Dimethyl sulfate	Organic chemical manufacturing	Severe eye and skin burns, laryngeal edema, late-onset pulmonary edema	0.1 ppm	100 ppm
Dioxane	Solvent	Irritant to eyes and mucous membranes. May cause pulmonary edema. Primarily systemic toxicants, hepatic necrosis, renal damage	25 ppm	1,500 ppm
Ethylene oxide	Fumigant, sterilizing agent	Irritation of eyes, skin, respiratory tract; pulmonary edema, CNS depression	1 ppm	1,000 ppm

(continued)

Table 3 (continued)

Agent	Principal occupations exposed	Time-weighted main mechanism of injury	Average ^a	IDLH level ^b
Fluorine	Rocket fuel, uranium processing, manufacturing of fluorocarbons	Severe irritation of eyes, skin, mucous membranes, respiratory tract; pulmonary edema	1 ppm	25 ppm
Formaldehyde	Disinfectant, embalming fluid use, paper and photography industry	Direct action on mucosa of the eyes and respiratory tract; dermatitis, asthma (?)	1 ppm (0.8 ppm)	100 ppm
Glyphosate herbicides	Herbicide application	Acute mucosal erosions of mouth and upper respiratory tract. Damage to alveolar membrane. Gradual development of chemical pneumonitis (roundup pneumonitis)	—	—
Halon	Fire extinguishing, refrigerant	Cardiac toxicity, asphyxiation	—	1,000 ppm
Hydrogen chloride	Refining, dye making, organic chemical synthesis, pyrolysis in fires	Direct action on mucosa of the eyes and respiratory tract, tracheobronchitis	5 ppm	100 ppm
Hydrogen cyanide	Electroplating, fumigant work, steel industry	Systemic effects, asphyxiant	10 ppm	50 ppm
Hydrogen fluoride	Etching, petroleum industry, silk working, plastics, refrigerants	Direct action on mucosa of the eyes and respiratory tract, tracheitis	3 ppm	20 ppm
Hydrogen selenide	Ceramic and glass manufacturing, photocells	Irritation of eyes, nose, throat, delayed pulmonary edema	5 ppb	—
Hydrogen sulfide	Natural gas making, paper pulp, sewage treatment, tannery work, oil well prospecting	Systemic and local effects, pulmonary edema, and asphyxia	10 ppm	300 ppm
Magnesium oxide fumes	Welding, alloy, flare, filament making	Systemic effects	15 mg/m ³	—
Manganese fumes	Foundry work, battery making, permanganate manufacture	Systemic effects, possible predisposition to pneumonia, neurotoxicity	5 mg/m ³	—
Mercury fumes	Electrolysis	Direct action on mucosa of the eyes, gastrointestinal tract, and lung; interstitial pneumonitis, systemic effects	0.1 mg/m ³ (0.05 mg/m ³)	28 mg/m ³
Methane	Mining	Simple asphyxiation	—	—
Methyl bromide	Fumigating, dye and refrigerant making	Direct action on mucosa of the eyes and respiratory tract	5 ppm	2,000 ppm
Methyl isocyanate	Pesticide manufacturing	Direct action on mucosa of the eyes and respiratory tract; tracheitis, pulmonary edema, chronic airways obstruction	0.02 ppm	20 ppm
Methylene chloride	Solvent, paint remover, aerosol propellant	Primarily a CNS depressant, mild mucous membrane irritant, asphyxiant due to metabolism of carboxyhemoglobin	50 ppm	1,000 ppm
Natural gas	Mining, petroleum refining, power	Asphyxiant	—	—

(continued)

Table 3 (continued)

Agent	Principal occupations exposed	Time-weighted main mechanism of injury	Average ^a	IDLH level ^b
Nickel carbonyl	Metallurgy, coal gasification, petroleum refining	Pulmonary edema, delayed toxic pneumonitis	0.001 ppm	30 ppm
Nitrogen dioxide	Arc welding, dye and fertilizer making, farming, silo filling	Irritant to respiratory tract; tracheitis, pulmonary edema, bronchiolitis obliterans	5 ppm (1 ppm)	50 ppm
Osmium tetroxide fumes	Alloy making, platinum hardening	Direct irritation of respiratory tract	0.002 mg/m ³	1 mg/m ³
Ozone	Arc welding; air, sewage, and water	Direct irritation of respiratory tract	0.1 ppm	10 ppm
Paraquat	Herbicide	Minor irritant of mucous membranes; epistaxis, iritis, severe fatal pulmonary fibrosis. Primary absorption through skin or GI tract	0.1 µg/m ³	1 mg/m ³
Phosgene	Chemical industry, dye and insecticide making, refrigeration, fire fighting	Direct irritation of respiratory tract; pulmonary edema	0.1 ppm	3 ppm
Phosphine	Semiconductor manufacturing, fumigant	Severe respiratory irritant, pulmonary edema, asphyxiant. Inhibits electron transport and combination of heme to iron	0.3 ppm	100 ppm
Platinum, soluble salts (mist)	Alloy, mirror making, electroplating, catalysis, ceramic work	Asthmatic reactions	0.002 mg/m ³	—
Propane	Cooking, heating	Simple asphyxiation	1,000 ppm	20,000 ppm
Sulfur dioxide	Bleaching, ore smelting, paper manufacture, refrigeration industry	Direct action on the respiratory tract; bronchitis, exceptional pulmonary edema	2 ppm (0.5 ppm)	100 ppm
Sulfur pentafluoride	Production by-product of synthesis or degradation of sulfur hexafluoride	Severe pulmonary irritant, pulmonary edema	10 ppb	1 ppm
Titanium tetrachloride	Metallurgy	Highly corrosive to skin, eyes, mucous membranes—contact with water liberates hydrogen chloride and chloride. Pulmonary edema, endobronchial polyposis	—	1,000 ppm
Toluene-2,4-diisocyanate	Production of polyurethane foams, plastics, paints, wire coatings	Severe mucous membrane irritant to eyes, skin, respiratory tract; bronchitis, asthma, pulmonary edema	5 ppb	100 ppb
Trimellitic anhydride	Epoxy resins, paints, dyes, pharmaceuticals	Cough and upper airway irritation, rhinitis and asthma, flu syndrome, pulmonary disease, anemia syndrome	5 ppb	2 mg/m ³
Vanadium pentoxide fumes	Glass, ceramic, alloy making, chemical industry (catalysis)	Direct action on respiratory tract; bronchitis, asthma	0.5 mg/m ³ (0.05 mg/m ³)	70 mg/m ³
Zinc chloride fumes	Dry cell making, soldering, textile finishing, smoke grenades	Direct action on respiratory tract, irritant; pulmonary edema	1 mg/m ³	2,000 mg/m ³

(continued)

Table 3 (continued)

Agent	Principal occupations exposed	Time-weighted main mechanism of injury	Average ^a	IDLH level ^b
Zinc oxide fumes	Welding, cutting galvanized steel	Systemic effects, metal fume fever	5 mg/m ³	–
Zirconium chloride	Metallurgy	When heated, emits chloride fumes. Can produce pulmonary edema. Damages mucous membranes	5 mg/m ³	–

Table 5 Gas solubility and toxic effects

1. Solubility and chemical reactivity are the major explanations for the site of action and severity of a toxic inhalation
2. Corrosive gases, such as ammonium, sulfur hexafluoride (SF ₆), mustard gas, methyl isocyanate, and silicone tetrachloride (SiCl ₄), produce intense upper airway symptoms, such as severe coughing, conjunctivitis, burning in the nose, laryngeal edema, and facial burns
3. Exposure to a soluble irritant gas can be estimated as significant if the conjunctivae are inflamed, the face is erythematous, and the nose and throat are red and irritated; this suggests a dose high enough to produce upper and lower airway damage

may be related to the fact that irritant gases may induce bronchospasm, resulting in the maldistribution of toxic effects in the lung. This belief is supported clinically by the observation that patients may have patchy pulmonary infiltrates, sparing otherwise normal areas of the lung, and heterogeneous abnormalities diagnosed by

Table 6 Determinants of severity of lung injury

radionuclide imaging studies [10]. The breathing pattern affects the extent of lower airway damage. If the respiratory rate is rapid and the tidal volume is small, much of the ventilation is simply moving gas in and out of the anatomical dead space. If the patient is breathing deeply and slowly, there is a greater amount of gas taken into the lower airways; clinically, this may be seen in an industrial accident in which an individual remains calm and walks slowly out of the area versus another who panics and runs. If the gas immediately causes coughing, the patient is taking large vital capacity breaths before each cough, which causes deep inhalation of the gas into the lower airways. Similarly, another individual in the same environment who does not cough or

sneeze has a lower exposure. The amount of gas inhaled into the terminal airways and alveoli can vary substantially between one individual and another. Gases that are slowly reactive or not reactive in the lung, such as carbon monoxide or arsine, simply pass through the alveolar gas-exchanging surfaces into the blood. Highly reactive gases are taken up primarily by the bronchial mucosa, and there is little of the gas accessible to the circulation.

The effective dose of a gas is a function of the vapor concentration of the gas, the amount inhaled, and the amount retained in the lung. In addition, effective doses depend on the uptake of that gas in a target cell or tissue, mainly the bronchial and nasal mucosa. The effective dose is the amount of the gas that participates in a damaging reaction. This amount differs from the amount inhaled; a certain amount is going to be exhaled as dead space gas. The calculation of the effective dose of formaldehyde necessary to produce a squamous cell carcinoma of the nasal cavity in rodents is a more reliable indicator of risk than the calculation of dose simply from vapor concentration and the amount inhaled [11].

Concentration and duration of exposure further affect the kinetics of the metabolism of a gas in various tissues. In low concentration, a gas may be taken up entirely by the mucosa in the upper airways, but at higher concentration, its uptake and metabolism may be saturated, causing the effective concentration of the gas to increase with time in the lower airways. This concentration of the lower airways increases as the absorption and metabolism of the gas reaches zero-order kinetics in the upper airway. The concentration also is affected by the inhalational rate; rapid, deep breaths, which occur with coughing or exertion, overwhelm the metabolism and uptake in the upper airways.

The biological effect of a gas depends on its water or lipid solubility. Gases that are lipid soluble, such as chloroform, ether, or other halogenated hydrocarbons, may produce central nervous system effects and little or no respiratory irritation. Methylene chloride is an exception to this rule in that it has mild irritating effects and in extremely high doses may cause pulmonary edema [12]. Water-soluble gases are taken up by

the respiratory mucosa and produce their effects in the lung and upper respiratory tract and would be expected to have no systemic effects. The irritant effect of a gas is based on its reactivity or the intensity of the chemical reaction that occurs in the respiratory tissue. The reaction rate of these chemical reactions influences the site of action of the gas. A rapid reaction may occur with gases, such as formaldehyde, in which the reaction occurs so rapidly that little of the inhaled dose gets beyond the nose. Gases with moderate levels of chemical reactivity, such as chlorine, may have a greater effect on lower airways because a greater percentage of the gas bypasses the upper airway. The predominant site of action of irritant gases is influenced by the anatomy of the pulmonary airways. Miller and Kimble [10] have shown that the concentration of ozone in the airways tends to reach a maximum concentration at the 16th through 17th generation of airways. This concentration is affected predominantly by the fact that as the number of generations of airways increases, the cross-sectional diameter of the surface area of the lung increases exponentially. There is a tremendous dilutional effect of an inhaled breath of gas by this rapid change in surface area, resulting in a maximum concentration at airway generation 16 or 17. Bates [13] suggested this idea in 1972 before the elegant studies of Miller and Kimble. Additional studies have confirmed that the smaller airways and respiratory bronchioles seem to be the major site of damage after a significant inhalational exposure to the reactive gas chlorine [14].

The potential of a gas to produce a concentration high enough to be potentially injurious can be estimated by simple calculation. If one knows the vapor pressure of the gas, one can estimate the concentration at room temperature, or 25 °C, by

$$\text{ppm} = (\text{vapor pressure @ } 25^{\circ} \times \text{mmHg}/760) \times 10^6 \quad (4)$$

A compound with a vapor pressure of less than 0.76 mm Hg at room temperature attains an air concentration of less than 1,000 ppm at the saturated vapor concentration. A vapor pressure of

0.076 mm Hg would produce a concentration of 100 ppm. Using this simple formula, one can calculate the concentration of a gas in a potential exposure situation. The value of 760 mm Hg represents sea-level atmospheric pressure. At other altitudes, the relevant atmospheric pressure should be substituted.

The vapor pressure of a gas is the partial pressure exerted by that gas and is a reflection of its volatility. Factors that affect the volatility can affect the dose of an exposure greatly. Methylene diisocyanate has a low vapor pressure, so it is not volatile at room temperature. When heated or mixed with an organic solvent that has a high vapor pressure, however, its vapor pressure increases, and it may be volatilized. In the case of mixture with an organic solvent, the latter serves as a carrier. Vapor pressure and density of gases are important in understanding the dynamics of a toxic exposure. Chlorine gas, which is more than 2.5 times the density of air, tends to flow into low-lying areas. This tendency explains why there can be large differences in levels of exposure in a group of exposed workers when there is only a few feet difference in elevation between one worker and another. Depending on the climatic conditions, this gas may stratify in a green cloud that flows across a floor into low areas. A worker who is in a low area may get an exposure of ten times greater than a worker who is in a location that is a few feet higher on a scaffold or walkway. This type of property of a gas explains why gas exposures tend to produce a heterogeneous degree of injury in a group of workers. In a group of workers involved in an accident at a paper mill where chlorine was released from a tank car, the umbilical hose that went from the tank car to the bleaching plant became detached from the bottom of the tank car. Because this occurred in the winter when the building was heated and the gas was cold, the heat of the building acted as a source of convection that drafted the dense cold chlorine to the roof, where a group of construction workers has heavily exposed. People at ground level who were working in the mill had no significant exposure despite their close proximity to the gas leak [9]. Calculating the dose,

temperature, humidity, wind direction, and other climatic conditions may influence the dose to a given individual. Because the upper airway acts as an absorber of water-soluble gases, any condition that causes mouth breathing, such as allergic rhinitis or an upper respiratory infection, might result in more significant lower airway injury because of the lack of absorption by the nose. The determinants of severity of lung injury are summarized in Table 6.

Terminology

The following terms commonly are used to quantify the health effects of toxic inhalants:

Dose: Dose is the quantity of the compound received by the subject.

IDLH: Immediate danger to life or health (IDLH) is commonly used as in Table 3 and reflects data from human experience and animal models.

LD₅₀: The lethal dose (LD)₅₀ is the dose that kills 50% of the exposed population and reflects extrapolated data from animal models and therefore is only a rough estimate of human toxicity.

ID₅₀: The incapacitating dose (ID)₅₀ is the dose that incapacitates 50% of the exposed population.

Ct: The concentration time (Ct) is a measure of exposure to a vapor or aerosol. The concentration in the air and the time of exposure govern the dose received, as do rate and depth of respiration. It is assumed that when the product of concentration and time is constant, so is the biologic effect over a limited range of concentration and time. This assumption may not be true except in a laboratory setting, but for purposes of making some type of estimate of exposure, a steady-state hypothetical value is used. Concentration is expressed as mg/m³ and time as minutes so that the Ct is expressed as mg·min/m³.

LCt₅₀: The lethal concentration time (LCt)₅₀ is the Ct that would kill 50% of the exposed population; this reflects extrapolation from animal models.

ICt_{50} : The incapacitating concentration time (ICt_{50}) is the Ct that would incapacitate 50% of the exposed population.

RD_{50} : The respiratory depression (RD_{50}) is the concentration that would cause respiratory depression by 50% in 10 min of exposure.

Pathophysiology of Toxic Effects

The early responses to the inhalation of irritant gases are primarily reduced ciliary function, increased mucus production, submucosal edema, and smooth muscle constriction. These are followed by mediator-induced airway inflammation, causing symptoms of retrosternal pain, cough, and dyspnea. Aminophylline and isoproterenol attenuate leukotriene generation by lung mast cells and prevent lysosomal degranulation of neutrophils, a key component of airway inflammation. In the lungs, swelling of type 1 pneumocytes occurs, followed later by capillary leakage due to damage of the basement membrane of epithelial cells. These changes in the cytoskeleton affect the intercellular junctions, causing them to pull apart. The role of cyclic adenosine monophosphate (cAMP) in regulating epithelial cell permeability has become an area of great interest, because it has been reported that cAMP decreases the permeability of epithelial cells by altering the structure of tight junctions [15, 16].

The health effects of irritant gas or vapor exposure depend on their physiochemical properties and specific host factors. The extent of adverse effects may vary among individuals when exposed to the same agent and concentration.

Oxidant-Related Injury

Oxidant-related injury causes increases in pulmonary vascular pressure and epithelial permeability. Studies with the oxidant tert-butyl hydroperoxide have shown that pulmonary phospholipid oxidation yields arachidonic acid via phospholipase A₂ (Fig. 1). Arachidonic acid is a substrate of the cyclooxygenase pathway, leading to the synthesis of prostaglandin F_{2α} (Fig. 2), which is a pulmonary

Fig. 1 Pathways of release of arachidonate from phospholipids by two-step processes. DAG diacylglycerol, IP inositol phosphate (From Ref. [148], p. 214)

vasoconstrictor. Arachidonic acid also is a substrate for the lipoxygenase pathway (Fig. 2), which increases vascular permeability [17].

A variety of prooxidants produce cell injury by causing the formation of reactive oxygen species that overwhelm the natural defense mechanisms of the cell. The reactive oxygen species include superoxides and hydrogen peroxide, which may produce highly reactive elements that damage cell membranes. Glutathione peroxidase is a key enzyme involved in the detoxification of lipid peroxides, and the maintenance of reduced glutathione is essential for glutathione peroxidase function. Several other thiol compounds have been shown to be capable of protecting animals against oxygen toxicity and against lung damage from bleomycin-induced and paraquat-induced lung injury [18–20]. The discovery that glutathione constitutes the major source of a low-molecular-weight thiol in mammalian tissue for the purposes of detoxification has resulted in great interest in the substitution of other thiol compounds, such as *N*-acetylcysteine, in the treatment of phosgene and other toxic inhalations.

Studies by Miller and coworkers [21] on the inhalation of ozone in animal models suggested that the maximum dose of ozone is found in the respiratory bronchioles. Some human data from clinical studies suggest that the respiratory bronchioles are the primary target for ozone [13]. Studies suggest that there is damage to the respiratory bronchioles in many workers exposed to a variety of soluble and moderately soluble gases. Patients may be asymptomatic, but one or more years after the exposure they may have evidence of either a

Fig. 2 The biosynthesis of prostaglandins, prostacyclin, and thromboxane from arachidonate. Compounds with biologic action are shown in *boxes*. There are two forms of cyclooxygenase (COX): One (COX-1) is constitutive and occurs in most cell types, and the other (COX-2) is induced in inflammatory cells by inflammatory stimuli. The current nonsteroidal anti-inflammatory drugs (NSAIDs) act mainly on COX-1. *HHT* 17-hydroxy-heptadecatrienoic acid, *IFN- γ* interferon- γ , *PG* prostaglandin, *TX* thromboxane. of action of antiinflammatory drugs. The arachidonate metabolites are "eicosanoids." The glucocorticoids inhibit transcription of the gene for cyclooxygenase-2, which is induced in inflammatory cells by inflammatory mediators. The effects of prostaglandin E2 (PGE2) depend on which of the three receptors for this prostanoid are activated; see text. [148], p. 214, 215)

low residual volume or restrictive disease or reduced diffusing capacity on pulmonary function tests. Some of these patients go on to develop reactive airways dysfunction syndrome and have evidence of bronchial hyperreactivity [22].

Inhalational Fevers

Metal fumes, fluorocarbon pyrolysis fumes, or organic dusts rich in endotoxins may produce a series of febrile reactions usually characterized by chills, fever, chest tightness, myalgias, joint aches, and fatigue. This group of inhalational fevers has been called a variety of names, such as *zinc welding shivers*, *silo unloader's disease*, *humidifier fever*, *grain fever*, *mill fever*, *polymer fume fever*, *metal*

fume fever, and *organic dust toxic syndrome*. These conditions all are characterized by a subclinical alveolitis not apparent on chest x-ray or pulmonary function tests except in unusually severe cases. Inhalational fevers are associated with a neutrophilic predominance on bronchoalveolar lavage and a systemic leukocytosis. Their systemic effects are transient [23]. Inhalational fevers can be confused with toxic reactions to gases and vapors. Inhalational fevers are discussed in greater detail in the chapter on Toxin-Induced Pulmonary Syndromes.

Solubility

Water-soluble gases, such as ammonia, sulfur dioxide, formaldehyde, and methyl isocyanate,

produce irritation to mucous membranes and the cornea and usually are characterized by significant ocular symptoms, such as redness of the eyes and, with heavy exposure, delayed onset of cataracts. First-degree burns of the face may be present, and there is likely to be erythema of the nose and symptoms related to the nose and posterior pharynx because most of these gases are absorbed in the mucous membranes in the upper airway. These highly water-soluble gases also are likely to cause pharyngeal injury, reflex laryngospasm, and laryngeal obstruction because of the rapid onset of laryngeal edema [24–26].

Gases with intermediate water solubility, such as chlorine, tend to produce more upper airway irritation. Because of its intermediate solubility, chlorine may produce upper and lower airway injury. Gases with low water solubility, such as phosgene or oxides of nitrogen, produce little in the way of upper airway irritation unless they are in very high concentrations, but they produce intense damage in the lower airways and pulmonary edema. Phosgene gas was used during World War I and was responsible for approximately 80% of the deaths from gassing. Its vapor density is 3.4 times that of air. Its high density made it an ideal agent in the days of trench warfare. This gas has a relatively low odor threshold and is said to smell like freshly mown hay. The low-solubility gases are more likely to produce the delayed onset of symptoms and delayed onset of pulmonary edema. Agents associated with pulmonary edema or chemical pneumonitis are listed in Table 7.

Two properties, water solubility and chemical reactivity, are the most useful in predicting the site of damage of a substance. Most water-soluble gases dissolve in the mucous lining of the upper respiratory tract; mucus contains about 95% water and acts as a sink for water-soluble gases. After dissolving in the mucus, the gas molecules can diffuse in the underlying epithelial cells of the respiratory tract, where they can cause damage. Most of the molecules that hit mucus fail to dissolve and reenter the airspace. The remaining gas molecules may be pulled farther down the airspace, where they again are exposed to more moist mucus until they get to the lower airways. There is a concentration gradient from the upper airway to

the lower airway when one takes a breath of a highly soluble gas, in that it is continually being absorbed onto the mucous blanket of the respiratory tract from the upper airway through the lower airway. The concentration may be low by the time it reaches the terminal airways. This gradient is overcome, however, when the gas is inhaled in a high concentration, and this explains why lower airway damage can occur after an exposure to a highly soluble reactive gas (see Table 5).

The opposite is true for the fate of a gas with low water solubility because there is little uptake in the upper respiratory tract, and the most important factor is the surface area of the lower airway. The greater uptake tends to occur in regions of high surface area, such as the alveoli in terminal airways, compared with regions of lower surface area, such as the trachea and major lobar bronchi. Highly reactive low water solubility vapors are absorbed primarily in the alveolar area, and this is the site of their damage. This explains why patients with phosgene exposure may present with pulmonary edema and little in the way of upper respiratory signs or symptoms, unless the gas is present in high concentrations.

Smoke Inhalation

The pathophysiology of the acute lung injury associated with smoke inhalation suggests that the influx of neutrophils is the major source of acute lung injury via the release of a variety of cytokines resulting in increased vascular permeability. Lung injury from smoke has shown that activated neutrophils seem to play an important part in the pathogenesis of the lung injury. Depletion of neutrophils with nitrogen mustard

significantly decreases smoke-induced increase in lung microvascular permeability to protein [27]. The neutrophils are recruited from the microcirculation via the upregulation of selectin-type adherence molecules on the endothelial surface. Neutrophils adhere to the endothelium, and intercellular adhesion molecule type 1 facilitates the diapedesis of the neutrophils across the endothelium into the interstitium of the lung, where they release free oxygen radicals and proteases. Sulfo Lewis C is a compound that blocks the uptake of neutrophils out of the microcirculation [14]. These studies and other studies blocking CD-18 or CD-11b in the lung injury model of acute acid instillation in rabbits suggest that compounds that prevent neutrophil migration into the lung might be useful in certain models of inhalational injury in humans [28]. Another approach that has been evaluated is the blockage of interleukin-8, which is the major chemotactic factor for neutrophils. Pretreatment with an anti-interleukin-8 antibody reduces smoke-mediated increase in the bidirectional transport of protein across the alveolar epithelium. This suggests that interleukin-8 is important in the pathogenesis of smoke inhalational injury and probably is important in other sources of inhalational injury.

A group from Taipei showed in a wood smoke model in guinea pigs that evidence of airway injury occurs within 5 min after wood smoke inhalation, followed 2 h later by parenchymal injury. The lung injury involves the release of tachykinins. Tachykinins are neuropeptides released from C-fiber nerve endings that invoke a variety of proinflammatory mediators that have the ability to increase production of oxygen radicals. The airway and late parenchymal injury is blocked by tachykinin receptor antagonists, particularly to the tachykinin NK1 receptor [29].

Clinical Presentation and Life-Threatening Complications

Davy, a British chemist, synthesized phosgene (carbonyl chloride; CAS: 75-44-5) in 1812. Phosgene is a colorless gas. The boiling point of

phosgene is 8.2 °C (47 °F); it is extremely volatile. Phosgene is hydrolyzed rapidly in the human body with the formation of hydrochloric acid and carbon dioxide ($\text{COCl}_2 \rightarrow \text{HCl} + \text{CO}_2$). Phosgene has a vapor density 3.4 times that of air, making it an ideal war gas because it accumulates in low-lying areas, such as foxholes and ditches. The first battlefield use of phosgene was at Verdun in 1917 by Germany. During and immediately after exposure, there is likely to be coughing, choking, a feeling of tightness in the chest, nausea, and occasionally vomiting, headache, and mild lacrimation. The presence or absence of these symptoms is of little value in immediate prognosis. Some patients with severe cough fail to develop serious lung injury, whereas others with little sign of early respiratory distress develop severe delayed pulmonary edema after 2–24 h. Exposure to moderate concentrations triggers lacrimation and the unique complaint that smoking tobacco produces an objectionable taste. High concentrations may trigger rapidly developing pulmonary edema with attendant severe cough, dyspnea, and frothy sputum. The onset of pulmonary edema progresses over 2–6 h and is predictive of severe injury. High concentrations may produce a severe cough with laryngospasm that results in sudden death; this possibly could be due to phosgene hydrolysis, which releases free hydrochloric acid at the level of the larynx. In the first 12 h after toxic inhalant exposure, depending on the intensity of exposure, a substernal tightness with moderate resting dyspnea and prominent exertional dyspnea becomes evident. These symptoms often are a prelude to the characteristic development of pulmonary edema. Initially small, then greater, amounts of thin airway secretions may appear. The delayed, insidious onset of severe pulmonary edema often has resulted in a patient's being medically evaluated and discharged from the medical facility, only to return some hours later with severe and occasionally lethal pulmonary edema.

Irritant gases, such as phosgene, can cause local irritation of airways, which induces bronchoconstriction, which may produce a rise in pulmonary artery pressure, increasing the pressure gradient and causing pulmonary edema

[30–33]. Airway damage can affect the surfactant system, which results in destabilization of airways with atelectasis and decrease in pulmonary compliance [34]. These substances may induce transformation of the cell surface and lead to dose-related production and liberation of cytokines, which affect capillary permeability and produce pulmonary edema. Intrapulmonary shunting from ventilation/perfusion inequalities produces hypoxia, which can enhance lung injury further. The role of various mediators in the production of epithelial injury has great implications regarding treatment. Various studies have been performed on the role of arachidonate mediators in the pathogenesis of lung injury from phosgene [17]. In many other types of oxidant lung injury, there is increased synthesis of lipoxygenase products (see Fig. 2) after phosgene exposure, which seems to contribute to the pathogenesis of pulmonary edema [15, 35]. Drugs that inhibit the lipoxygenase pathway possibly might reduce pulmonary edema in phosgene-exposed individuals [36].

Nitrogen Oxides and the Risk of Bronchiolitis Obliterans

Oxides of nitrogen, such as nitrogen dioxide, characteristically produce a triphasic illness [37]; this is called *silo filler's disease* if it is related to exposure to stored silage. Initial presentation may be cough, wheeze, dyspnea, central chest pain, fever, sweating, and weakness. Physical examination at this stage may reveal wheezes and crackles, and the patient may be hypotensive and cyanotic. The patient's x-ray can be normal or show pulmonary edema. This phase of the illness resolves, and the patient may enter the second phase of being relatively asymptomatic; 2–8 weeks later, the patient develops the third phase with symptoms of obliterative bronchiolitis – fevers, chills, wheeze, cough, dyspnea, and chest pain associated with wheezes and crackles on physical examination. The chest x-ray can be normal or show diffuse, small nodules. The late development of bronchiolitis obliterans is a serious complication that, based upon case reports and small case

series, usually responds to steroids but can progress if not treated properly and may be fatal [38, 39]. In cases in which there is a possibility of bronchiolitis obliterans, consideration of a course of steroids for 8 weeks seems a reasonable prophylaxis for the prevention of life-threatening bronchiolitis. Table 8 lists toxic chemicals that are typically associated with bronchiolitis obliterans.

Riot Control Agents

In the past, riot control agents consisted largely of chloroacetophenone (CN) and chlorobenzylidenemalononitrile (CS) [40]. Common symptoms following exposure include rhinorrhea, lacrimation, skin irritation, chest pain, coughing, and dyspnea. Case reports have documented an association with ocular toxicity, dermal burns, laryngospasm, acute lung injury, and death following exposure to high concentrations in an enclosed space or during exertion [40, 41]. Due to toxicity, CN and CS have been largely replaced with oleoresin capsicum (OC), commonly known as *pepper spray*, which while considerably less toxic has also been associated with pneumonitis and death in case reports [42, 43]. In a case series of 22 patients, inhalation of zinc chloride, used in smoke bombs, resulted in temporary ground glass opacities on x-ray computed tomography scan and

a restrictive lung disease pattern on pulmonary function tests [44].

Patient Evaluation

When evaluating a patient with an exposure to a water-soluble gas (see Table 2), careful examination of the upper respiratory tract may provide clues estimating whether the exposure has been sufficient enough to be associated with lower airway damage. If a patient who had been exposed to the soluble gases sulfur dioxide and ammonia presents with watery, teary eyes; red face; chronic rhinitis; red, sore nose; erythema of the posterior pharynx; hoarseness; and difficulty swallowing, one can assume that this has been a heavy exposure that may produce lower airway damage [24–26]. The corollary is that if an individual is exposed to highly soluble gas, such as ammonia, and there are no upper respiratory signs or symptoms, it is unlikely that they have inhaled a dose high enough to cause lower airway disease. This caveat applies only to individuals who are exposed to high concentrations of a highly water-soluble gas of short duration. Lower levels of exposure for longer periods may produce airway damage with minimal signs of conjunctival, cutaneous, and upper airway irritation [45]. When a patient is exposed to a low-solubility gas (see Table 2), such as phosgene, there would be expected to be fewer upper respiratory tract findings, and it is important to observe the patient for 6–24 h as it may take several hours for pulmonary edema to develop. It is wise to observe such a patient in a closely monitored environment for at least 24 h if there is evidence that there has been a high exposure to one of the low-solubility gases that has occurred or if the patient is hypoxemic, tachypneic, or in any respiratory distress. Table 7 lists the common toxic gases and fumes associated with pulmonary edema and chemical pneumonitis. Referral to the list of agents that may cause pulmonary edema (see Table 7) should help the physician determine if a given exposure is likely to result in acute or delayed pulmonary edema.

These same principles are less reliable in evaluating fire-related inhalational injuries. Signs such as singed nasal hair, carbonaceous sputum, and soot in the posterior pharynx are not reliable predictors of lower airway damage [46–48]. Facial burns are seen frequently with and without fire-related inhalational injuries and lack specificity and sensitivity. More than 80% of patients with a fire-related inhalational injury do not have facial burns [47, 48].

Respiratory symptoms, such as severe coughing, respiratory distress, stridor, tachypnea, restlessness, wheezing, and chest tightness, suggest the possibility of significant airway injury and require prolonged observation and assessment with frequent arterial blood gases, oximetry, chest x-rays, pulmonary function tests, and possibly fiber-optic bronchoscopy or laryngoscopy.

Indications for ICU Admission

1. Acute respiratory failure requiring ventilatory support
2. Patients demonstrating respiratory deterioration
3. Need for nursing/respiratory care not available in lesser care areas such as floor or intermediate care unit
4. $\text{PaO}_2 < 50 \text{ mmHg}$
5. Hemodynamic instability
6. Greater than 10% body surface area burn
7. Chronic comorbid conditions predisposing the patient to respiratory compromise

Adapted from Ref. [147] [Level of Evidence III].

Central nervous system symptoms, such as dizziness, headache, confusion, disorientation, hallucinations, and seizures, may reflect signs of hypoxic brain damage due to nonirritant gases, such as carbon monoxide or cyanide, or head trauma from a fall related to being overcome by toxic fumes or other problems. Drug or alcohol abuse is common in victims of industrial accidents and house fires, and a toxicological screen may be helpful in the evaluation of the confused patient.

An elevated carboxyhemoglobin concentration may be useful in diagnosing carbon monoxide poisoning. A serum lactate greater than 10 mmol/L in a patient following smoke inhalation or greater than 8 mmol/L in those not exposed to smoke may indicate cyanide exposure and prompt administration of a cyanide antidote [49, 50] [Level of Evidence II-2]. Cardiac arrhythmias commonly accompany tissue hypoxia, and an electrocardiogram and continuous cardiac monitoring are advisable. Some patients with inhalational injuries may complain of a substernal burning chest pain that may be confused with the pain from a myocardial infarction.

Oximetry

For patients showing major signs or symptoms after gas inhalation, arterial blood gases should be obtained. Room air arterial blood gas determinations are the most useful. The PO_2 may be normal, however, in patients with toxic hemoglobinopathies, such as patients with high levels of methemoglobin or carboxyhemoglobin. Pulse oximetry does not detect these abnormal hemoglobins correctly and measures only normal saturated and desaturated oxyhemoglobin. An oximetry panel (co-oximeter), which contains measurements of carboxyhemoglobin, methemoglobin, total hemoglobin, and oxyhemoglobin, is necessary to evaluate patients' levels of carboxyhemoglobin and methemoglobin and should be performed routinely in fire exposures and inhalational injuries of unknown type. Pulse oximetry may give a false sense of security in patients exposed to carbon monoxide, oxidant gases that produce methemoglobinemia, or cyanide gas from fires.

Pulmonary Function Tests

When there is significant damage to the lower airways, spirometry may be abnormal early in the

clinical course, particularly with fire-related inhalational injury. However, normal spirometry does not exclude or predict late-onset pulmonary edema or damage to the upper airway [51]. Spirometry frequently is normal in the presence of mild restrictive disease from an inhalational injury, and measurement of lung volumes is helpful when available. Pulmonary function tests may aid in evaluating for long-term respiratory dysfunction and injury but offer little value in the acute setting. Airflow obstruction may be due to reactive airways dysfunction syndrome related to epithelial injury [22] or anatomical airway narrowing related to chronic scarring after airway inflammation. The most common late abnormality is an isolated reduction in residual volume [52]. After chlorine exposure, restrictive changes in lung function progress slowly and may not be detected for 2 or more years [53]. Isolated reduction in lung diffusion may occur but usually is accompanied by reduction in lung volumes. Methacholine challenge testing should be performed only in patients with signs and symptoms of bronchial hyperreactivity after the third month. Early transient bronchial hyperreactivity, which lasts only several days to weeks, is commonly seen after an irritant gas exposure. Detection of early bronchial hyperreactivity is not always predictive of long-term airway injury and irritability. Long-term consequences of irritant gas exposure are variable (Table 9). Most patients recover completely [54], but others may develop long-term airway irritability, restrictive lung disease, obstructive lung disease, bronchiectasis, bronchostenosis, or bronchiolitis obliterans.

Table 9 Long-term effects of acute toxic inhalation

Complete resolution of symptoms

Bronchostenosis (e.g., mustard gas)
COPD or restrictive lung disease
Low residual volume

COPD chronic obstructive pulmonary disease

Key Points

1. Significant exposures to low-solubility agents (phosgene, NO) may not demonstrate respiratory deterioration until 6–24 h following exposure [II-2].
2. Treatment consists primarily of respiratory supportive care [II-1].
3. Other potential therapies include anti-inflammatory medications, nebulized sodium bicarbonate, bronchodilators, nebulized heparin, and surfactant [II-1].
4. Given the differences in pathophysiology, therapies ineffective in treatment of ARDS due to sepsis and nontoxic causes may still benefit patients with toxic inhalation-induced pulmonary injuries [III].
5. The location of a toxic inhalation victim can significantly impact the severity of exposure and extent of injury [II-2].

*Levels of evidence given in brackets

Treatment

The treatment of a toxic inhalation is primarily supportive, including oxygenation, bed rest, analgesia, and mechanical ventilation, if necessary. Contaminated clothing that might further increase the absorption of a substance through the skin should be removed, and the patient may need to be decontaminated before entering the acute care area. Consultation with a medical toxicologist or poison center (1-800-222-1222 in the USA) may aid in determining the amount of decontamination necessary. This care is outlined in Table 10. Any superficial burns should be treated conservatively. Careful attention to the eyes is important because there may be corneal burns, ulcerations, infection, anterior and posterior synechiae, corneal opacification, glaucoma, retinal atrophy, and the late development of cataracts with heavy exposures. Proper eye care, particularly copious irrigation, is essential immediately after the exposure.

Table 10 Strategies for managing inhalational injury^a

1. Decontaminate the victim (e.g., remove chemical-soaked clothing) [II-2]
2. Obtain admission arterial blood gas and cooximetry studies [III]
3. Start high-flow 100% oxygen [III]
4. Examine the patient for eye injuries, flush eyes, and treat if inflammation is noted [III]
5. Record evidence of facial burns, nasal burns, and pharyngitis [III]
6. If the victim is hoarse and has difficulty phonating, consider immediate intubation [II-3]
7. Observe the patient for delayed pulmonary edema for 24 h if the patient is hypoxemic or has been exposed to a low-solubility gas, such as phosgene [II-3]
8. Chest x-rays are not usually helpful unless the patient has significant hypoxemia, marked dyspnea, or basilar rales [II-3]
9. Avoid excessive crystalloids which may contribute to pulmonary edema [III]
10. Keep the patient on bed rest because low-level exercise can induce pulmonary edema in a vulnerable patient with subclinical pulmonary edema [II-3]

^aLevels of evidence given in brackets

The eye is often the forgotten organ in a patient with an acute irritant gas exposure [25]. Generally the eye needs to be irrigated for at least 20 min or, if this is a case of ammonia exposure, until the pH of the conjunctival sac decreases to less than 8.5. Ocular lavage needs to begin in the field at the site of injury if possible. No ointment should be applied to the eye, and contact lenses should be removed to ensure adequate irrigation [Level of Evidence III]. The patient should be referred to an ophthalmologist as soon as possible [55].

The patient who presents with tachypnea and stridor, particularly with some hoarseness, is at a high risk of developing progressive laryngeal edema and complete obstruction of the airway and should be considered for emergency expectant intubation. If signs or symptoms of upper airway damage are present, a prompt inspection of the larynx by a laryngoscope or fiber-optic bronchoscope is imperative because once sufficient edema develops, these patients are extremely difficult to intubate and may require an emergency tracheostomy [Level of Evidence II-3].

Exercise increases cardiac output and pulmonary artery pressures. This increase may unmask latent pulmonary edema, and the patient may die quickly if medical attention is not immediately available. Sedation and bed rest are recommended for the first 24–48 h [56, 57] [Level of Evidence II-3].

Corticosteroids

There has been some opinion that corticosteroids may prevent or decrease the severity of acute respiratory distress syndrome developing following a toxic inhalation [Level of Evidence III]. Based on prospective trials in the management of inhalational injuries in burn patients [58] and anecdotal reports, there is no clear benefit to administering corticosteroids for the prevention or treatment of acute respiratory distress syndrome (ARDS) secondary to toxic inhalation. Meta-analyses of multiple randomized controlled studies regarding prophylactic or early institution of high-dose systemic steroids suggested that steroids are not useful and may be harmful in ARDS and sepsis [59, 60]. A subsequent review of 33 trials randomizing a total of 3,372 patients reached similar conclusions [61]. However, a small minority of patients enrolled in these studies had ARDS induced by toxic inhalation. Differences in the pathophysiology of the most common causes of ARDS (sepsis and trauma) limit the extrapolation of these findings to inhalational injury-induced ARDS.

In patients who are likely to develop bronchiolitis obliterans or bronchiectasis at a later date, corticosteroid therapy is probably helpful [62] [Level of Evidence II-3]. Patients with silo filler’s disease or patients exposed to high doses of nitrogen dioxide particularly fall into this category. Patients with high exposure to zinc chloride may develop chronic airway disease and generally are considered candidates for systemic steroids [Level of Evidence III]. If the patient has been exposed to a gas in sufficient quantity and of the type commonly associated with bronchiolitis obliterans (see Table 8), such as nitrogen dioxide,

it is recommended that the patient be kept on moderately high doses of prednisone (20–40 mg/day) for about 8 weeks [62] [Level of Evidence II-3].

There is suggestive evidence in an animal model of chlorine inhalation of improved lung function and reduced pathologic changes in the airways with high doses of dexamethasone given after exposure [63] [Level of Evidence III]. Because of the sporadic nature of acute gas inhalational injury and the heterogeneity of the human response, however, controlled studies adequate to examine the effectiveness of corticosteroids are unlikely ever to be performed in cases of acute toxic gas inhalation. In summary, corticosteroids are recommended only in exposures which may lead to the development of bronchiolitis obliterans [Level of Evidence III].

Pentoxifylline

The role of tumor necrosis factor- α (TNF- α) has been evaluated in a smoke inhalational injury model in sheep [64]. Lymph and alveolar lavage specimens failed to show elevated levels of TNF- α . These researchers were unable to establish a role for this drug in smoke-induced pulmonary injury in sheep. Pentoxifylline, a methylxanthine normally used to treat peripheral vascular disease by decreasing red blood cell rigidity, is a potent inhibitor of TNF- α [65]. It has been shown to inhibit polymorphonuclear leukocyte phagocytosis and to decrease superoxide anion production in polymorphonuclear neutrophils and monocytes. Pretreatment of rats with pentoxifylline prior to phosgene exposure decreased the formation of inflammatory markers [66]; however, it was not found to be helpful in the treatment of acute lung injury after phosgene exposure in rats [67]. Theoretically, TNF- α blockade should be useful, but the animal data have been discouraging. Human data are mixed and often confused by the fact that pentoxifylline was not used as a single agent [68]. Combination therapy with nitric oxide looks promising in the prevention of reperfusion lung injury after lung transplantation in humans [69]. The role of this

type of combination therapy in smoke or irritant gas inhalation is unknown [Level of Evidence III].

Aminophylline and Terbutaline

Another methylxanthine, aminophylline, seems to protect against phosgene-induced acute lung injury in rabbits [70–72]. Treatment of 80–90 min after exposure reduced acute lung injury. Aminophylline may protect against acute oxidant lung injury by (1) a direct antipermeability effect, (2) inhibition of permeability-inducing sulfidopeptide leukotrienes, (3) a direct or indirect antioxidant action, (4) maintenance of cAMP concentration required to keep tight cellular junctions, and (5) possible vasodilatory mechanisms [73]. Treatment with terbutaline improved gas exchange and lung edema in swine exposed to chlorine gas [74]. The practical implication of this research is that commonly available, reasonably safe, low-cost drugs, aminophylline and terbutaline, may be effective in the acute management of an acute inhalational injury and should be given early in the clinical course in clinically significant inhalational gas exposures which may lead to acute lung injury [Level of Evidence III].

N-Acetylcysteine

Glutathione is a water-soluble antioxidant that protects against free radical injury. Free radicals are thought to be the source of cytotoxic damage in many models of irritant gas injury. Chlorine combines with tissue water to form hypochlorous and hydrochloric acid, which diffuse into cells and react with amino groups of cytoplasm, forming *N*-chloral derivatives that cause nascent oxygen to be released through a series of chemical reactions. The oxidative effects are responsible for the major toxic effects and respiratory damage. Glutathione protects cells from oxidant injury via the regulation of several biologic processes. *N*-Acetylcysteine is a compound that maintains glutathione levels in oxidant stress and has been shown to protect against endotoxin-induced and

radiation-induced damage [18, 20, 75]. It protects against bleomycin-induced damage in mice and protects alveolar type II cells from paraquat toxicity [76, 77]. In a rat model, pretreatment with intravenous *N*-acetylcysteine decreased chlorine-induced pulmonary injury [78]. *N*-Acetylcysteine also has been shown to protect against phosgene-induced lung damage by intratracheal administration in rabbits, but it was not protective when administered by the intravascular route [72, 79]. A Finnish group used *N*-acetylcysteine in the management of three patients with severe zinc chloride smoke inhalation [80]. One of the three patients survived. A randomized, double-blinded, placebo-controlled trial of 264 patients found no significant benefit of *N*-acetylcysteine for the treatment of idiopathic pulmonary fibrosis [81]. A small randomized trial of 36 patients with early ARDS and no evidence of infection found decreased pulmonary lipid peroxidation with *N*-acetylcysteine therapy (50 mg/kg in 250 mL of 5% dextrose in water) but no statistically significant clinical differences; however, extrapolation of these human studies to toxic inhalation-induced lung injury is limited [82]. The aforementioned dose could be tried by nebulizer, but this compound can be irritating and may induce bronchospasm in humans and should be given with 2.5 mg of albuterol solution every 4 h [82]. There have been no clinical trials with this drug in humans for acute inhalational injury, but a short course of the drug for 24–48 h in the appropriate clinical setting may be considered [Level of Evidence III].

Ibuprofen

Ibuprofen is a commonly used antipyretic and anti-inflammatory compound that originally was shown to modify lung injury response to aspiration in dogs in 1982 [83]. It has free radical scavenging and iron-chelating mechanisms of reducing acute oxidant lung injury [17, 84, 85]. It has been shown to be protective against acute lung injury from paraquat in rats [86], smoke inhalation in rabbits [87], and burn injury in sheep [89]. Ibuprofen also has been shown to

protect against acute lung injury from phosgene in mice, rats, and rabbits [36, 70]. Its role in the treatment of acute inhalational injury in humans is unknown. If used in humans, a dose of 25–50 mg/kg of ibuprofen (well in excess of normal therapeutic dosing) would be roughly compatible to the doses used in animal studies. Sciuto and coworkers [66] reported in a phosgene-exposed rat model that ibuprofen was effective alone and useful when combined with pentoxifylline. This study plus the study by Stewart and associates [87] in an animal smoke inhalational model suggest that further human trials are necessary before ibuprofen can be recommended [Level of Evidence III].

Antibiotics, Chest Physical Therapy, and Bronchodilators

Prophylactic antibiotics have been suggested because the sloughing of the tracheal mucosa offers a good culture medium for bacteria; however, there is no evidence that they are beneficial [58]. Antibiotics should be withheld, unless there is clinical evidence of an infection [Level of Evidence III]. Chest physical therapy and high-frequency percussive ventilation may be helpful in patients with mucus plugs and thick secretions [Level of Evidence II-3]. Bronchodilators should be administered if a patient has evidence of bronchospasm [Level of Evidence I].

Nitric Oxide

Nitric oxide attenuates acute lung injury in humans and animals [90]. Nitric oxide decreases release of key mediators of inflammation, downregulates the intrapulmonary inflammatory process, decreases pulmonary artery pressure, decreases pulmonary artery remodeling, and improves oxygenation [91–93]. Nitric oxide decreases vascular permeability [94] and theoretically should be an ideal agent for the management of irritant-induced pulmonary edema. A multicenter European trial containing 268 patients from 43 university and regional hospitals showed

the safety and effectiveness in reducing pulmonary artery pressure, improving oxygenation, and reducing the rate of severe respiratory failure in patients with ARDS but did not produce a statistically significant improvement in survival [95, 96]. Other investigators have thought that inhaled nitric oxide was useful in burn patients with respiratory failure, but this information is largely anecdotal [97]. The negative effects of nitric oxide are that in high doses (80 ppm), it paradoxically increases inflammation and activates the coagulation system in mice [98–100]. A meta-analysis of nine trials (1,142 patients) found nitric oxide does not reduce mortality in adults or children with ARDS [61]. Furthermore, a multicenter, randomized, placebo-controlled study in patients with acute lung injury not due to sepsis found no difference in duration of ventilatory support or mortality [101]. While no studies have specifically evaluated the efficacy of nitric oxide for toxic inhalation-induced injury, based upon the aforementioned studies, it is not recommended at this time [Level of Evidence III].

Perfluorocarbons

Perfluorocarbon partial liquid ventilation (PLV) is the intrapulmonary administration of perfluorocarbons. Perfluorocarbons are liquids with low surface tension and high oxygen-carrying capacity. Cell models, animal models, and human studies have demonstrated significant improvements in oxygenation and decreased pulmonary injury in nonchemically and chemically induced ARDS when compared to mechanical ventilation [102–104]. Theoretically, PLV could lavage chemicals persisting in the bronchopulmonary tree, but adequate studies are lacking. A single trial in which 312 patients with ARDS were randomized to mechanical ventilation, low-dose PLV, and high-dose PLV found a nonstatistically significant increase in mortality in the PLV groups with a statistically significant higher complication rate [105]. Further research is necessary to determine if this therapy provides any clinical benefit [Level of Evidence III].

Exogenous Surfactant

Both in vivo and in vitro studies have demonstrated the ability of toxic gases to inactivate pulmonary surfactant [106]. A single animal study in sheep found surfactant administration to significantly improve survival following hydrocarbon aspiration [107]. Multiple case reports have documented improvement with administration of surfactant in humans following hydrocarbon aspiration [108–110].

Two multicenter, randomized, double-blinded trials evaluating a total of 448 patients found surfactant did improve gas exchange during the initial 24 h following administration but had no effect on mortality or ventilator-free days [111]. Only one of the 448 patients had ARDS due to direct toxic injury to the lung. While research is limited, based upon mechanism and case reports, the administration of surfactant (dosed upon manufacturers recommended dosing for respiratory distress syndrome) following a significant toxic inhalation injury is reasonable [Level of Evidence III].

Sodium Bicarbonate and Calcium Chloride Inhalation

The concept of neutralizing halogen-induced acids has been suggested in animal studies, and sodium bicarbonate nebulization has been shown to improve arterial blood gases after chlorine exposure in an animal study [112]. Sodium bicarbonate also has been used successfully in human case reports and is recommended by some authors [113, 114]. These treatments are anecdotal, however, and there is no consensus of efficacy of this therapy. A randomized, double-blinded, placebo-controlled study comparing 44 subjects treated with nebulized salbutamol, IV prednisone, and either nebulized placebo or sodium bicarbonate found a significantly higher FEV1 240 min after treatment but no statistically significant difference in quality of life scores [115]. However, differences in the two treatment groups, the small sample size, and lack of evaluation for long-term outcomes limit the utility of the study's findings. Given the safety

profile and lack of significant adverse effects, treatment of chlorine inhalation with 4 mL of 4.2% nebulized sodium bicarbonate solution is a reasonable intervention [Level of Evidence II-2].

Exposure to hydrofluoric acid (HF) can lead to fatal dysrhythmias secondary to the fluoride ion binding serum calcium, thereby inducing a relative hypocalcemia [116]. While the majority of cases reported to poison centers are due to cutaneous exposure or ingestion, during an 11-year period, nine deaths reported to the US Occupational Safety and Health Administration involved HF. Of those nine deaths, five were administered with calcium; however, it was administered 90 min after the exposure in two victims and over 6 h after the exposure in another [117]. A case series of 13 patients exposed to HF mist at concentrations greater than 50 times the short-term inhalation limit during a single industrial accident reported all 13 surviving following the rapid administration of 4 mL of a 2.5 calcium carbonate solution mixed with normal saline and delivered with 100% oxygen as a nebulized treatment [118]. While no randomized trials are available, given the lethality of HF inhalation and the safety of nebulized calcium gluconate, rapid administration of the aforementioned dose is recommended for any inhalational HF exposure [119] [Level of Evidence III]. Significant exposures may also require intravenous calcium administration [Level of Evidence III]. Further details regarding HF injury and its treatment can be found in the chapter on Hydrofluoric Acid Toxicity.

Treatments for Smoke Inhalation

Smoke inhalational injury remains the primary determinant of burn-related mortality [119]. Smoke-related inhalational injury is complex and is due to exposure to a mixture of varying concentrations of carbon particles, liquids, heat, chemicals, and toxic gases – largely carbon monoxide, hydrogen chloride, nitrogen oxides, hydrogen cyanide, acrolein, hydrogen sulfide, hydrogen fluoride, phenol, sulfur dioxide, formaldehyde, and various other gaseous pyrolysis products. Thermal injury affects predominately the upper airway, and chemical injury from toxic gases or

chemicals attached to inhaled carbon particles, such as aldehydes and organic and inorganic acids, affects the upper and lower airways. The damage to the alveolar and capillary epithelium may occur simply from the release of cytokines from peripheral tissues after a large surface area burn, without any evidence of fire-related direct effects on the airways. This cytokine release and the effects of overhydration may produce pulmonary edema not directly related to the inhalation of smoke. Smoke itself may activate a variety of hematogenous mediators that further enhance smoke-related damage. It is important to distinguish effects relating to burns and fire-related smoke inhalational injury from inhalational irritant exposures because the usual mechanisms of lower airway injury from the latter are different from the mechanisms usually occurring from the former.

Inhalational injury associated with burns from fires comprises approximately one quarter of patients admitted to a burn unit. The subglottic or supraglottic edema following this type of inhalational injury may obstruct the airway. This type of obstruction may develop slowly over the first 12–24 h due to the initial hypovolemia and other factors. Chemicals in the smoke (see Table 1) are primarily responsible for the airway injury. Smoke particles may facilitate further airway damage via the chemicals absorbed to the surface of these particles.

Fiber-optic bronchoscopy is useful in evaluating burn patients for airway injury by showing carbonaceous material, airway edema, erythema, ulcerations, hemorrhage, blisters, or ischemia [120]. At the time of bronchoscopy, intubation, preferably over the bronchoscope, should be performed in those patients with clinically significant upper airway edema or hypoxia/hypercarbia refractory to noninvasive modalities. Because the upper airway effects from smoke inhalation may progress slowly over 18–24 h, consideration must be given to reevaluation by bronchoscopy or laryngoscopy at 24–48 h in patients who demonstrate worsening respiratory function. Tracheostomy through burn tissue generally is contraindicated because of the substantial risk of infection from the wound to the airway and the

airway to the wound [121]. Xenon-133 ventilation scanning has been used in burn patients to detect airway injury missed by fiber-optic bronchoscopy [122] [Level of Evidence III]. It has a high sensitivity, but there are false-positive results in patients with obstructive airway disease. It has been used to assess airway injury in other types of inhalational injuries [10].

The efficacy of chest x-rays has not been studied in a systematic fashion, but they are probably not necessary in every patient, particularly after a low-level exposure and normal blood gas values. The chest x-ray is useful, however, for acute inhalational injuries related to smoke inhalation and for more severe inhalational injuries accompanied by hypoxia [123] [Level of Evidence III]. The chest x-ray is sensitive to changes in lung water and is useful in following severely burned patients, in whom changes in lung water are related to sepsis, hydration, pulmonary infection, and ARDS [124].

Mortality from smoke inhalation is due mainly to the inhalation of carbon monoxide, cyanide, and other toxic gases listed in Table 3. Carbon monoxide is the most common cause of death from smoke inhalation [125]. Routine carboxyhemoglobin concentrations should be evaluated in any smoke inhalation setting. Cyanide toxicity is more difficult to diagnose but should be suspected in an obtunded victim with a blood lactate greater than 10 mmol/L. Often carbon monoxide and cyanide levels are elevated in the same victim, and dual toxicity should be considered in the obtunded smoke inhalation victim regardless of the carboxyhemoglobin level [126]. Carbon monoxide and cyanide toxicity are discussed in more detail in chapters on carbon monoxide and cyanide.

The treatment of burn-related inhalational injury is not standardized. Early investigators tried nebulized dexamethasone and aerosolized gentamicin unsuccessfully to treat patients with inhalational burn injury [58]. Drugs that reduce free radical formation and cytokine production currently are being investigated, and inhaled nitric oxide has been tried in an effort to improve ventilation/perfusion matching and decrease pulmonary artery pressure [49]. In a sheep model of

inhalational burn injury, ibuprofen reduced lung lymph flow and inhalational injury [127]. Using the same sheep model, pentoxifylline improved pulmonary function [89], and dimethyl sulfoxide with heparin reduced lung injury [128]. These treatments are still experimental. None of these therapies can be recommended at this time for the management of non-burn-related inhalational injury or burn patients [Level of Evidence III]. The strategy for management of smoke inhalation is related in part to the presence or absence of direct thermal injury to the airways.

Most smoke inhalation victims do not have direct thermal injury because of the low heat transfer capacity of heated air. The trachea is an amazingly effective heat exchanger. Moritz and colleagues [129] showed in dogs that when air at 270 °C was blown into the larynx of dogs, the temperature of the inspired air declined to 50 °C in the trachea. By contrast, steam has high heat transfer capacity (approximately 4,000 times that of air) and may cause intense upper and lower airway damage. The presence of large numbers of soot particles in the nose, pharynx, and sputum is another clue to possible thermal injury because carbon particles may be fairly efficient mechanisms for transfer of heat and irritating chemicals adsorbed on their surface, causing subsequent damage to the upper and lower airway [121]. The site of damage depends on particle size, with the larger (>10 µm) particles trapped in the nose and upper airway. Particles 3–10 µm become trapped in the tracheobronchial tree.

The site of toxic particle and gas deposition influences the type of airway injury. Airway casts and large particles may cause atelectasis. Smaller toxic particles may damage smaller airways, resulting in alveolar overdistention during mechanical ventilation and a high risk of barotrauma. The presence of irritants in the airway results in a large increase in bronchial blood flow and hyperemia of the airways. This large change in bronchial blood flow is thought to be a major factor in the development of pulmonary edema after smoke inhalation [130, 131]. Currently, there is no agreed-upon treatment for burn-related inhalational injury. Some centers in the USA use a combination of *N*-acetylcysteine

and albuterol solution every 4 h, then nebulized heparin, 5,000 U every 4 h, so that patients receive a nebulized drug every 2 h. Nebulized heparin (see later) seems to be safe and does not affect blood clotting in this dose range. Other national burn centers do not use any standard drug therapy for patients with inhalational injuries.

Nebulized Heparin Therapy in the Treatment of Respiratory Burns

Heparin is a member of a group of compounds called *glycosaminoglycans*, which are highly acidic, negatively charged polysaccharides. These are remarkable compounds with many anti-inflammatory effects, including effects on toxic oxygen metabolites, cytokines, histamine, bradykinin, TNF, prostaglandins, and many other inflammatory mediators; heparin is best known as an anticoagulant [132]. Heparin influences the remodeling of collagen at the site of wound healing, which results in earlier epithelialization of burns. Pulmonary problems are less frequent in heparin-treated burn patients [133]. In 1993, Cox and associates [134] reported that heparin improves oxygenation and minimizes barotrauma after smoke inhalation in an ovine model. Nebulized heparin has demonstrated a reduction pulmonary damage markers in rats exposed to chlorine gas and has been investigated in burn units in an effort to reduce bronchial cast formation [49]. A study in children with cutaneous and pulmonary burns associated with destruction of the ciliated epithelium and airway casts showed a response to nebulized heparin with a reduction in mortality compared with controls [135]. The usefulness in fire-related burns suggests that nebulized heparin might prove useful in chemical burns of the airway, particularly ammonia-related inhalational injury [Level of Evidence III].

Mechanical Ventilation

Mechanical ventilation with low tidal volumes and positive end-expiratory pressure is currently the

standard of care for inhalational injuries associated with severe abnormalities of gas transport [136–139] [Level of Evidence I]. Inhalational injuries from irritant gases or burns produce spotty areas of intense injury, leaving other areas in near-normal condition presumably protected by regional bronchospasm [140] this originally was reported by Winternitz [9] in studies on dogs exposed to irritant gases at the end of World War I. Mechanical ventilation with high tidal volumes and positive end-expiratory pressure may improve oxygenation but at the same time may overinflate the least affected areas of the lung, causing barotrauma and hyperinflation with increased pleural pressure causing reduced venous return, cardiac output, and oxygen delivery. Low tidal volume ventilation and positive end-expiratory pressure now are recommended for all types of lung injury and are associated with better survival from ARDS [141]. Low tidal volumes seem to reduce epithelial and endothelial injury [142]. Permissive hypercapnia is well tolerated as long as satisfactory oxygenation is maintained [143]. More recently, there has been interest in high-frequency percussive ventilation [144]. Some investigators believe that it helps mobilize secretions in burn patients with fibrin plugs. This treatment still is considered investigational.

Extracorporeal Membrane Oxygenation

In cases of life-threatening pulmonary injury refractory to mechanical ventilation and other therapies, venovenous extracorporeal membrane oxygenation (ECMO) has been reported in case reports with varying degrees of success [145, 146]. Further research is necessary to determine if a significant mortality benefit is provided by this resource intensive and costly therapy [Level of Evidence III]. The use of ECMO is discussed in more detail in the chapter on ECMO and Cardiopulmonary Bypass in the Critically Poisoned Patient.

Criteria for ICU Discharge*

1. Adequate oxygenation and ventilation without ventilatory support (significant

(continued)

exposures to low-solubility agents may not demonstrate respiratory deterioration until 6–24 h following exposure) [III].

2. When a patient's physiologic status has stabilized and the need for ICU monitoring and care is no longer necessary [III].
3. When a patient's physiological status has deteriorated and active interventions are no longer planned, discharge to a lower level of care is appropriate [III].

Adapted from Ref. [147].

*Levels of evidence given in brackets

Special Populations

Treatment guidelines are largely the same regardless of the individual exposed; however, certain populations are at higher risk of clinically significant illness following exposure. Pediatric patients' small airways, increased respiratory rate, and large lung volume to body mass ratios place them at higher risk of airway compromise and hypoxia. Furthermore, their shorter stature may result in higher exposures to higher-density gases collecting close to the ground. Decreased baseline lung functions and chronic disease predispose the elderly or those with underlying pulmonary disease to toxic inhalational exposures.

Exertion during a toxic inhalational exposure results in an increased minute ventilation rate and corresponding quantity of toxic gas [40, 41]. Furthermore, exertion following an exposure increases the development of pulmonary edema in rat models [56, 57]. This has important implications for rescue workers and individuals attempting to flee from the scene of a chemical release. Exertion should be considered in the determination of a patient's risk for significant pulmonary injury following a toxic inhalational exposure [Level of Evidence III].

Caustic or corrosive substances take many forms, with varied concentrations, pH, and formulations. The intent behind the exposures is likewise diverse and ranges from the suicide attempt in an adult to an exploratory taste in a young child. The heterogeneous nature of the substances, patients, circumstances, clinical presentations, and spectrum of injury makes diagnosis and treatment a daunting task for the clinician.

Definition

A caustic, or corrosive, is any substance that can destroy tissue chemically and is classically thought of as acids or alkalis. In addition, there are caustic agents that do not fit this simple classification, such as Clinitest tablets, creosote, ingredients in electric-dishwasher detergent and laundry detergent, phenol, zinc chloride, and surfactant [1–3]. The terms *caustic* and *corrosive* are also sometimes used to describe oxidizing agents (potassium permanganate), desiccants, vesicants (mustard gas), and protoplasmic poisons (hydrofluoric acid) [4]. Most recently, concentrated packets of laundry detergent, often referred to as “pods,” have arisen as a cause of aerodigestive tract burns in children who ingest them [5].

Epidemiology

The epidemiology of caustic exposures has changed over the years. The introduction of new cleaning products to the public, notably liquid lye in 1967, increased the incidence of caustic ingestions. At that time, the prototype of new liquid drain cleaners contained 30% sodium hydroxide. Because of the sudden increase in severe morbidity that followed the introduction of this product in the USA, the US Poison Prevention Packing Act of 1970 and the US Federal Hazardous Substance Act of 1973 were passed, mandating the use of child-resistant caps for products containing 2% or more of an alkaline caustic and the reduction of concentration of cleaning substances. Designed to protect young children from dangerous substances found around the house, these Acts are responsible in part for a decline in serious pediatric caustic injuries.

The exact incidence of caustic ingestions is unclear due to the manner in which these data are reported. Poison center data are gathered passively and are subject to underreporting. Moreover, caustic and corrosive substances are classified as cleaning substances and are therefore difficult to distinguish from other household cleaners. Nonetheless, caustics continue to be one of the most frequently reported substances involved in human exposures [6]. In the 2014 Annual Report of the American Association of Poison Control Centers National Poison Data System, caustics accounted for more than 30,000 exposures [6].

Children younger than 6 years old account for the greatest number of exposures to caustic substances, with most exposures being unintentional. Hawkins and colleagues [7] reported in 1980 that children younger than 5 years old accounted for nearly half of the caustic exposures in their series. These data closely resemble data reported from poison centers in 1998, in which 129,000 children younger than 6 years old represented nearly twice the number of all persons older than age 19 exposed to cleaning substances [6].

Suicidal patients are the next greatest number of patients with caustic ingestions. Although the number of intentional ingestions is a fraction of the number of unintentional exposures, they

account for nearly 80% of all serious injury requiring a major intervention.

Pathophysiology

Many factors contribute to the ability of a caustic substance to cause damage. Concentration, quantity, viscosity, contact time with tissue, pH, and titratable reserve all may be important in making caustics dangerous [8–13]. One *ex vivo* study examined esophageal damage when exposed for 10 s to 4%, 10%, and 22% sodium hydroxide. Histologic damage progressed from the mucosa to serosa as concentration increased [14]. People with suicidal intent more commonly ingest large amounts of caustic agents. The lesions found in these cases often are more extensive, and injury also involves the stomach and duodenum [8]. Burns are more common in areas of the esophagus where passage of the caustic agent may be delayed, such as at the crossing of the aorta and the left main bronchus [8, 15]. A pH of 12.5 has been cited as crucial for production of esophageal ulcerations from sodium hydroxide [13]. The contribution pH makes to the nature of a caustic injury is not straightforward, however [16]. Phenol and zinc chloride, two well-known caustic agents, have nearly neutral pHs.

Titratable reserve is defined as the volume of neutralizing substance required to bring the pH of a caustic to approximately that of a normal esophagus. In one study, titratable reserve correlated better than pH in predicting the production of esophageal injury [17]. Although titratable reserve helps explain causticity, it was not standardized for acids and bases and liquids and solids, and it does not correlate with resulting tissue strength after an exposure [18]. The best that can be said of pH and titratable reserve is that they help define the dangerous properties of a caustic agent but are only a few of the important characteristics to consider.

A caustic agent potentially can damage any tissue to which it is exposed. This may include the eyes, skin, larynx, lungs, gastrointestinal tract, and other intrathoracic and abdominal organs. Some caustics may also exhibit systemic toxicity,

such as hydrofluoric acid-induced hypocalcemia and metabolic acidemia from acid absorption.

It was historically suggested that acids caused maximum damage to the stomach and minimal injury to the esophagus, whereas alkalis caused injury in the reverse pattern. Before 1965, lye was available to the public only in solid form [19]. Although there are reports of suicidal patients mixing these crystals in water before drinking, many times ingested crystals would adhere to mucosal surfaces on initial contact, injuring the pharynx and upper esophagus, whereas a less viscous acid agent would pass rapidly through the oropharynx to collect in the stomach. These types of injuries are likely at the root of this concept. In 1967, liquid lye became available to the public in the USA, and more extensive injuries were diagnosed. One study specifically addressed this question and found no difference in distribution of injury between acids and alkalis [20]. Alkalis remain available, however, as solids, as viscous liquids, and in a formula that is designed to generate a column of foam using hydrogen peroxide. Almost all acids are available exclusively as low-viscosity liquids.

Ingested liquid forms of caustics expose all mucosal surfaces to the caustic material. This tissue injury has been studied extensively over the years. Experimentally, tissue injury occurs within seconds of contact for acids and alkalis [9, 14, 21]. After experimental exposure to alkaline substances, esophageal mucosa grossly becomes gray and gelatinous. Fats and proteins become saponified as the tissue neutralizes the caustic in a reaction that releases heat and gas [22]. Microscopic evaluation of alkaline caustic injury to esophageal tissue revealed liquefactive necrosis of the mucosa with edema and inflammation [10, 21]. Ulceration of the mucosa follows, and there is widespread thrombosis of arterioles and venules [8–10, 21, 23]. Acid-induced injury is described as a coagulation necrosis with formation of a thick eschar that theoretically may limit tissue penetration and tissue damage. Despite this difference from alkaline-induced necrosis, strong acids, like strong alkalis, perforate the gastrointestinal tract and cause injury to other intra-abdominal organs and death. Acid exposures to the esophagus also are characterized

by edema and an acute inflammatory reaction [24, 25]. At the edge of the injury, polymorphonuclear leukocytes infiltrate, and granulation tissue begins to develop [8, 10, 26]. Depending on the severity of the injury, inflammation may extend through the muscle layer, and perforations may occur. In these cases, periesophageal and intra-abdominal tissues become affected as well.

After several days, the necrotic tissue is sloughed, edema decreases, and fibroblasts begin to proliferate. Ulcerations may persist for months, and the esophagus shortens [10]. This period also includes neovascularization and the deposition of collagen [10]. Adhesions form between pockets of granulation tissue in bands, which is where stricture formation begins [8]. With the progressive remodeling that takes place over the weeks to months following a significant injury, the lumen of the esophagus begins to narrow. When enough scar tissue collects in a small area, it forms a stricture [10].

The risk of stricture formation is related to depth and circumference of the injury [27]. The depth of injury can be established only by endoscopy and direct visualization of the mucosa itself. A grading system describes the various degrees of injury, which may be associated with a risk for stricture (Table 1) [7, 28]. Grade 1 injuries are characterized by superficial mucosal hyperemia and do not progress to form strictures [19, 20, 29–31]. Grade 2 injuries include submucosal and transmucosal

Table 1 Endoscopic grades of esophageal injury

Grade	Description	Risk of stricture formation
1	Superficial mucosal hyperemia	None
2A	Noncircumferential submucosal or transmucosal ulcerations with blistering and exudate	Rare
2B	Circumferential or near-circumferential submucosal or transmucosal ulcerations with blistering and exudate	75%
3	Severe, widespread tissue destruction with deep ulcerations and extensive necrosis	100%

ulcerations with blistering and exudate [7, 19, 29, 32]. These injuries are divided into subtype A, which are noncircumferential and rarely develop strictures, and subtype B, which are near circumferential or circumferential and progress to strictures in 75% of cases [32]. Grade 3 injuries are described as severe with widespread tissue destruction, deep ulcerations, and extensive necrosis [19, 29, 32]. These injuries progress to form strictures despite any mode of therapy provided and have a high incidence of perforation [30, 33].

Significant complications may accompany the various stages of injury and recovery. Immediately, life-threatening complications include airway compromise and perforation into a great vessel [15]. Complications such as perforation may lead to periesophagitis, mediastinitis, peritonitis, infection from normal flora [8], shock, and sepsis [10]. Other complications include esophageal dysmotility [34], erosion into a bronchial artery, and formation of aorto-esophageal and tracheo-esophageal fistulae [23, 35]. Survivors of lye ingestions who develop a stricture have a 1000-fold increased risk of squamous cell carcinoma of the esophagus with a latency of approximately 40 years [36, 37], although this risk assessment was not controlled for regarding alcohol abuse and smoking [15]. Additionally, acid ingestions can cause an acidemia that results from absorption of the acid itself. Ingestion of hydrochloric acid may result in a non-anion gap acidemia because hydrogen and chloride are absorbed and accounted for in measuring the anion gap, whereas ingestion of sulfuric acid might result in an anion gap acidosis because sulfate is not measured directly in the anion gap calculation. Hydrofluoric acid confers a unique toxicity by complexing with extracellular calcium to induce severe hypocalcemia, which may be fatal (see ► Chap. 102, “Hydrofluoric Acid”). Conversely, ingestion of an alkaline substance typically does not result in alkalemia or direct metabolic derangement.

Clinical Signs and Symptoms

When a caustic agent comes in contact with tissue, severe pain often ensues throughout the mouth, lips, tongue, and oropharynx [10, 20, 38, 39].

Aspiration or direct airway injury may lead to voice change and stridor [38]. As deeper tissues become involved, dysphagia, odynophagia, chest and back pain, and vomiting may occur [10, 20, 40]. Abdominal pain with fever and tachycardia may suggest a potentially severe injury.

Many patients who have ingested a caustic agent do not present with a classic constellation of clinical signs and symptoms, however, that allow for early recognition of injury [41]. There are many cases in which a patient is reported to appear clinically well with normal vital signs and a soft, nontender abdomen yet dies within several hours or is found to have severe injury to the gastrointestinal tract [42, 43]. Many studies have found that less than half of patients with esophageal or gastric injuries diagnosed by endoscopy experience abdominal pain or have tenderness [12, 20, 28, 40]. In addition, the nature of the substance ingested may modify the initial presentation. Acids (not alkalis) are sometimes considered to be anesthetic, perhaps due to eschar formation. An ingestion of phenol, which is used commonly as a topical anesthetic agent, may not feature pain as a clinical symptom. Coingestants such as ethanol used by suicidal patients that may alter their mental status or their ability to express themselves clearly may mask any evidence of pain.

The concept that the absence of clinical signs and symptoms does not add to history has been suggested repeatedly [11, 12, 20, 40, 44]. When considering pediatric cases, the absence of clinical findings is even less reassuring [12]. It is crucial for the examining physician to be suspicious of an injury when presented with a well-appearing patient whose history includes caustic ingestion.

Predictors of Injury

Several studies have attempted to identify signs or symptoms that could be used to identify patients with a mucosal injury requiring treatment. Examination of the face, lips, and oropharynx, while advisable, is of limited predictive value for esophageal injury [8, 19, 25, 45]. One study found that 37% of patients who did not have burns to their cheeks, lips, or oropharynx had esophageal burns

in one or more places as diagnosed by endoscopy, whereas only 50% of patients with burns to their cheeks, lips, or oropharynx were found to have visceral burns [44]. As mentioned earlier, the presence or absence of abdominal pain or tenderness is also a poor predictor of gastrointestinal injury. Often less than half of patients with esophageal burns complain of abdominal pain [29].

Several investigators have evaluated whether combinations of signs and symptoms can be used to predict injury. One study that evaluated 79 pediatric patients found that the presence of two or more of the signs vomiting, drooling, or stridor correlated to a grade 2 injury or worse by endoscopy [46]. Perhaps just as important was that no patient who had only one of these three signs had a positive finding by endoscopy. No patients in this study had only stridor as a sign. Another investigator found that all patients with an alkaline-induced injury showed some symptom of injury but that no single sign accurately predicted injury. When data from 63 patients of all ages who received esophagoscopy were examined for signs of oral burns, drooling, vomiting, abdominal pain, and dysphagia, no group of signs or symptoms could identify all patients with serious esophageal injury. The study's author found that a combination of signs had a positive predictive value of only 46%. These data may be limited in that they were gathered via poison center phone calls and because suicidal patients represented 25% of the patients who had esophagoscopy, 50% of whom had positive findings [29]. Still another author was unable to correlate injury to any signs or symptoms in a pediatric population. This study population may have been difficult to assess for dysphagia and abdominal pain or refusal to drink, however, given that 79% were 12–35 months old [41].

Patients who have obvious signs of intra-abdominal injury, have an airway emergency, or have an acidosis that may indicate necrotic tissue must be presumed to have a serious injury until proved otherwise [29, 47]. One study found that adults accounted for less than half of all hospital admissions for caustic ingestions but developed 81% of all esophageal injuries requiring treatment [7]. Because many of these injuries result from

suicide attempts, all patients who attempted suicide must be presumed to have serious damage until disproved by endoscopy. Asymptomatic adult patients with unintentional ingestions in most cases do not require endoscopy [29].

Studying patients with caustic ingestions is difficult. These patients do not present frequently, requiring many years to gather substantial numbers of patients. Often children and suicidal patients comprise the greater proportion of these patients and may be difficult to assess as a whole. The ideal prospective study would include communicative patients with unintentional ingestions, to reduce confounders such as coingestants and false histories, and would have a wide range of endoscopic findings.

Treatment

As with other injuries, the initial management strategy for patients with caustic ingestions is to secure the airway, breathing, and hemodynamic stability. All patients require vital sign assessment and a rapid evaluation of the airway, including visualization of burns to the oropharynx, cheeks, and lips and so-called dribble marks. Although the absence of these signs does not exclude injuries elsewhere, their presence more strongly indicates exposure to a caustic agent.

Stridor and respiratory distress are true emergencies, given the nature of the injury. A caustic substance that contacts the respiratory mucosa causes tissue softening, edema, and, in the worst-case scenario, perforation. Direct visualization of the vocal cords may be accomplished by fiberoptic nasopharyngoscopy and can provide crucial information regarding the nature of the airway injury. As with thermal burns to the airway, edema may increase rapidly, making delayed attempts to control the airway progressively more difficult. Any signs of airway compromise or respiratory distress should prompt action to secure the airway.

For patients who require intubation, the author recommends that the intervening physicians be the most skilled available for the best possible management of complications. Intubation using

a fiberoptic instrument or with a laryngoscope in which the vocal cords are visualized directly may be attempted. When possible, paralytic agents should be avoided prior to intubation because edema, softened or partially dissolved tissue, and bleeding may complicate attempts to intubate and ventilate with bag-valve-mask apparatus. A surgical airway may be required depending on injury severity and the physician's ability to secure the airway by other means. A surgical airway should be considered a second choice for airway management, however, because the presence of a tracheostomy may interfere with reconstruction of the esophagus at a later stage [47].

Along with airway management, large-bore intravenous access should be obtained. Blood analysis sufficient for the patient to go to the operating room should be sent, including hematocrit, electrolytes, coagulation studies, and a blood type and crossmatch. Hypotension may be corrected by infusion of crystalloid or blood as needed. In general, it may be useful to consider these patients similar to patients with thermal burns regarding the potential for significant shifts of fluid and changes in hemodynamic status.

Decontamination

Topical exposure to the skin or eyes by a strong caustic agent has the advantage of being relatively easy to detect and treat. Lavage with copious amounts of water or saline is a safe and effective means of diluting the caustic and removing it from the exposed tissue (grade 3 evidence). Topical polyethylene glycol for phenol exposures may reduce tissue injury as demonstrated in animal studies [48]. A paste containing calcium salts (calcium chloride or calcium gluconate) has been reported to ameliorate pulmonary injury after hydrofluoric acid inhalation [49]. Ocular exposures require rigorous, thorough lavage with water or saline to reduce the risk of injury (Grade III recommendation).

Gastrointestinal decontamination in this setting is seldom appropriate. Use of an orogastric tube or nasogastric tube to remove any caustic material that has pooled in the stomach carries

the risk of perforation through the softened mucosa. Activated charcoal does not adsorb caustics and obscures mucosal evaluation by endoscopy. Both methods can induce emesis, which increases the risk of aspiration, reexposes tissue to the caustic, and increases intra-abdominal pressure and the risk of perforation. The risks of conventional means of decontamination far outweigh the potential benefits (Grade III recommendation).

Dilution and Neutralization

Dilution and neutralization of caustics have been proposed to limit caustic tissue damage, but clinical and research experience do not consistently support this practice. Dilution is the process by which by the addition of a neutral pH solution such as water or milk, the concentration of a caustic can be decreased and theoretically lessen damage. Neutralization involves the administration of a solution with the opposite pH, such as lemon juice in the case of an alkaline caustic, to bring the ingested substance to a more physiologic pH. Unfortunately, the risks include emesis, further tissue damage, and in the case of neutralization the generation of an exothermic reaction with heat, gas, and increased intraluminal pressure.

Studies of both dilution and neutralization have been conducted *ex vivo* and *in vitro* with inconsistent results. An *in vitro* dilution study experiment added various household items, such as lemon juice or milk, to beakers containing Clinitest tablets or crystalline sodium hydroxide and showed significantly increased temperatures [50]. Other investigations have diluted acids and alkalis with water, milk, and saline in *ex vivo* esophagi and shown decreased histologic damage to mucosal cells [51–53]. Yet other studies failed to show an appreciable change in pH when acid or base was diluted with water *in vitro* [54]. Early studies showed severe injury when *ex vivo* esophagi were exposed briefly to acids or alkalis and then washed copiously with either water or a dilute neutralizing agent [9, 21].

Neutralization studies have shown similar limited results. One *in vitro* study showed mucosal protection from acid when treated with sucralfate

partly due to acid neutralization [55]. Another study found minimal temperature increases when *in vivo* esophagi were exposed to alkali and neutralized with orange juice [39]. Still another study demonstrated decreased histologic damage in *ex vivo* esophagi when alkaline injuries were neutralized with orange juice [56].

Considering the limited demonstrated efficacy of these therapies, combined with the sizeable risk, neither dilution nor neutralization is indicated (Grade III recommendation).

Endoscopy

Endoscopy has been called the *sine qua non* for evaluating patients with caustic ingestions [57]. Endoscopic evaluation has many advantages [22, 32, 57]. Before the 1950s, the rigid esophoscope was not widely available, and the presence of severe burns could be diagnosed only after dysphagia from stricture occurred [58]. As the use of endoscopy came into the mainstream, it became widely recognized as an important tool for evaluating these patients [4, 8, 25, 31, 33, 57, 59–61]. Generally accepted guidelines for endoscopy included not passing the instrument deeper than the first serious injury (Grade III recommendation). This restriction attempted to limit the number of perforations from the procedure, but it also limited the evaluation and increased the risk of underestimating the total injury. The flexible fiberoptic endoscope has a smaller outside diameter and largely has replaced the older, rigid instrument for these evaluations. Careful, slow advancement under visual control with minimal insufflation reduces the risk of complications. The endoscope may be guided gently through areas of severe injury (Fig. 1), unless frank necrosis or obliteration of the lumen precludes its advancement [32]. Use of the flexible endoscope is described repeatedly as safe and necessary, and many studies report having no complications from the procedure [32, 40, 62].

Controversy still exists regarding when endoscopy should proceed for a patient with a history of caustic ingestion. Although most authors are in favor of early endoscopy, the times that are

Fig. 1 Endoscopy after a caustic ingestion, which shows severe necrosis in the midesophagus

recommended range from less than 6 h to 48 h. Older studies tend to refer to later times, which may reflect its limited availability and the relatively greater risk found with rigid esophagoscopy. Bikhazi and colleagues [33, 63] referred to endoscopy as elective, whereas Middelkamp and associates [31, 61] changed their recommendation from 24 to 48 h in 1961 to 12 to 24 h in 1969. Only Friedman [28] specifically recommended not performing endoscopy before 12 h because “adequate time may not have passed for the injury to manifest, and therefore the examination may underestimate the damage.” Friedman [28] recommended waiting until 24–48 h pass for best results. Since the early 1980s, there has been a growing body of experts who recommend that endoscopy be performed as soon as the patient is stable in order for the procedure to recognize a full-thickness injury as early as possible [4, 15, 35, 62–65]. *In vitro* studies showed the immediate injury these agents can cause. There is no utility in waiting to make a definitive diagnosis for these patients because to do so invites disaster in a subgroup whose injuries and outcomes are notoriously unpredictable.

Advantages of Endoscopy in Caustic Ingestion

Allows for a definitive diagnosis providing a basis for treatment

Helps limit hospital stay and unnecessary treatment for patients with minimal or no injuries

Defines the degree and character of the injury and directs management

Helps to predict complications

Allows for confirmation of adequate healing

Radiologic Investigations

Chest and abdominal radiographs may provide useful information rapidly in the early stages of management. The presence of a widened periesophageal stripe, pneumothorax, pneumomediastinum, pneumoperitoneum, or pleural effusion indicates a perforation in the gastrointestinal tract and may obviate the need for further studies. Although many authors advocate the use of these tests [11, 12, 15, 24, 38, 43, 47], the sensitivity of radiographs seems to be low. Despite one study that showed lateral chest x-rays to be 98% sensitive compared with 80% for posteroanterior chest x-rays for finding intraperitoneal air [66], several authors reported no visible free air despite clear perforations found at laparotomy [43, 47].

At one time, contrast swallow studies were used as a standard diagnostic tool for these patients. The generated images could find areas of esophageal dysmotility, whereas extravasation of dye could be used to indicate perforation. Swallow studies have low sensitivities as well and are accompanied by risks for aspiration and inflammation. Water-soluble solutions are even less sensitive and must be anionic to avoid the risk of pulmonary complications if such solutions are aspirated [11, 12, 15]. In addition, no information is gained regarding the depth of mucosal injury, limiting its utility further.

Computed tomography (CT) may have a role in enhancing diagnosis of caustic injuries. While Cattani and colleagues [64] opined that CT has little utility, more recent studies demonstrate

some value in diagnosing the extent of injury [67–69]. Moreover, CT may reveal pulmonary infiltrates which would otherwise be missed and may be appropriate if CT is unsafe or the expertise to perform endoscopy is truly unavailable [69].

Management Plan Based on Endoscopic Findings

The character and the extent of the injury indicate the management plan and disposition of patients with caustic injuries. Because endoscopy is the best tool to establish the diagnosis, management is delineated in terms of endoscopic grade of injury. Grade 1 injuries do not develop complications of stricture or tumor. When patients tolerate oral feeding, they potentially may be discharged [32]. If endoscopy shows a grade 2A injury, patchy or linear but noncircumferential submucosal damage without stomach injury, oral feeding may be resumed cautiously as tolerated. There are no studies guiding the decision of when to resume oral feeding, so this is usually done on clinical grounds. Alternatively, a feeding tube may be passed with fiberoptic guidance to resume nutritional support. As with patients with thermal burns, patients with caustic injuries enter into a hypercatabolic state and require substantial nutritional support [10, 21]. A negative nitrogen balance resulting from injury and poor nutrition inhibits healing and increases the risk of infection [12]. Patients with these injuries rarely develop stricture or other complications. Follow-up endoscopic examinations can document appropriate healing and add to disposition planning.

Patients with grade 2B or worse injuries have similar complication rates and require a longer time to heal [32, 63, 66]. Zargar and colleagues [32] divide grade 3 injuries into subtypes A and B. Grade 3A denotes small scattered areas of frank necrosis, and grade 3B denotes extensive necrosis [32]. For patients with grade 2B or worse injuries, oral or tube feeding may be contraindicated. Total parenteral nutrition, gastrostomy, and jejunostomy are options that may be used for these patients because nutrition continues to be a crucial factor in their healing. The risk of

stricture formation for patients with grade 2B injuries is high, and the use of steroids and antibiotics may be beneficial (see the following discussion on steroids and antibiotics). In general, grade 3 injuries progress to strictures regardless of therapy, and grade 3B injuries have a high risk of infection and perforation as well. These patients require surgical consultation for early resection and should be monitored closely. Various case series in which endoscopy revealed injuries grade 2 or worse reported a mortality rate of 10–15% [7, 35, 70], and in cases in which endoscopy discovered a grade 3B injury, a mortality rate of 66% was reported [32].

Use of Steroids

The utility of steroids in the treatment of caustic injuries has long been a controversial topic. Corticosteroids inhibit the inflammatory response and theoretically prevent stricture formation. Early animal models demonstrated a decrease in stricture formation but not surprisingly an increase in steroid-induced complications. Steroids may mask infection in the patient, including a brain abscess in one report [71], and may weaken already injured tissue, increasing the risk of perforation.

Many authors report using steroids as a routine part of their treatment regimen [4, 8, 10, 12, 19, 28, 31, 42, 57, 58, 61, 72–75]. Most of these reports do not differentiate, however, between grades of injury with regard to outcome. Other case series concluded that there is no risk of stricture formation from grade 1 injuries and that grade 3 injuries progress to strictures regardless of therapy. Several reports support the use of steroids, but only for cases with grade 2 injuries that may form a stricture but for which this outcome is not considered inevitable [4, 12, 19, 28, 32, 42, 74]. One well-known but often misquoted study prospectively investigated the effect of steroids on stricture formation. Sixty children were randomized over 18 years and were evaluated by rigid esophagoscopy only as far as the first serious burn. The conclusion of the study, which differs from what is stated in the abstract, is that the study lacked the statistical power to show a benefit using steroids – a type II error [71]. One meta-analysis

of 13 studies, however, found a 20% reduction in the incidence of strictures among patients with grade 2 and grade 3 injuries who received steroids and antibiotics [30]. Most recently, a randomized control trial of children with only grade 2 injuries demonstrated a significant benefit from corticosteroids (1 g/1.73 m² per day for 3 days), reducing stricture formation by 20–30% and decreasing length of parenteral nutrition therapy [76].

Corticosteroids are therefore advised in patients with grade 2 injuries to prevent stricture formation (Grade I recommendation). An appropriate dose is 1–2 mg/kg/day of prednisolone for 2–3 weeks or 1 g/1.73 m² of methylprednisolone followed by a taper of similar duration [19]. Steroid therapy is used in conjunction with antibiotics because of the increased risk of infection [71].

Use of Antibiotics

Tissue disruption from caustic injury increases infection risk which may extend to the mediastinum and peritoneum. This risk is increased further with corticosteroid use because corticosteroids inhibit the immune response and may mask the clinical appearance of an infected patient. Although there are no outcome studies showing a benefit for their use, antibiotics are used routinely with corticosteroid use to decrease the risk of infection. In the absence of steroids, there are no data to support prophylactic antibiotic use. However, many patients will mount a febrile response to caustic injury which is indistinguishable from an early infectious process, and in reality most patients receive empiric parenteral antibiotics early in the course of illness.

Use of Antihistamines and Proton-Pump Inhibitors

Antihistamines and proton-pump inhibitors have been advocated for therapeutic use in the context of caustic injury. One study evaluating intravenous omeprazole therapy reported improved endoscopic healing [77]. Histamine antagonists have not been subject to controlled studies but may be of benefit

[78]. Experimentally, serine and glycine have exhibited cytoprotective activity against chemically induced gastric lesions in rats [79, 80]

Surgical Intervention

A review of the literature presents a fascinating look at the change in the philosophy of treatment for patients with caustic injuries. In the 1960s, physicians had to wait until an injury declared itself in the form of stricture before beginning treatment. With the increased use of endoscopy, treatment with steroids and antibiotics could begin earlier, but patients with severe injuries still were treated conservatively with a watch-and-wait attitude. Various therapeutic techniques evolved only to prevent stricture formation, whereas the prevention of death was given little consideration. A certain fatalistic attitude pervades the early literature.

The conservative approach to patients with caustic injuries, including observation, hydration, nutrition, and possibly antibiotics and steroids, is appropriate for patients with minor injuries. Likewise, the decision for surgery is clear when the patient shows evidence of a perforation by endoscopy or radiography or has abdominal rigidity or hypotension.

There are many patients, however, who have serious injuries without early signs or symptoms, thereby delaying surgical intervention. Several authors have reported patients who had serious injuries to the stomach, esophagus, and other intra-abdominal organs and died without manifesting signs of the impending catastrophe until late in their clinical course [42, 43]. These patients *might* have benefited from early surgical intervention.

Since the late 1980s, more authors have advocated an aggressive surgical approach to patients with caustic injuries to decrease morbidity and mortality. Indications for surgery vary by author. One group adopted an approach that included early endoscopy, immediate laparotomy for patients with grade 2 or worse injuries, and

immediate esophagogastrrectomy for patients with full-thickness necrosis [42]. When using this aggressive approach, this group showed a decrease in the incidence of stricture formation in patients with grade 2 injuries and a much improved survival rate among patients with grade 3 injuries compared with their own hospital's records when a conservative approach was used. They concluded that the risk of missing a full-thickness injury was greater than that of the procedure and that the watch-and-wait attitude was too dangerous.

Other authors have advocated surgery for massive necrosis or an arterial pH less than 7.0 [35, 43]. Wu and Lai [47] recommended surgery for generalized abdominal pain and tenderness, continuous bleeding in the gastrointestinal tract, pleural effusion, and ascites. Although there is some debate as to whether laparoscopy provides an adequate examination of potentially injured tissues [64], many surgeons agree that the most important factor contributing to mortality is delay to diagnosis, necessitating an aggressive surgical approach if a transmural necrosis is suspected [15, 43, 65]. When managing patients with extensive necrosis or patients who may have a full-thickness injury, urgent surgical intervention including laparotomy and resection can be lifesaving (Grade III recommendation).

Lathyrogens

Lathyrogens are compounds that inhibit the activity of lysyl oxidase, the enzyme responsible for cross-linking collagen and providing tensile strength [75]. The formation of a more pliant scar can enhance dilation of the stenosis. Experimentally, many studies have attempted to attenuate stricture formation or enhance the manipulation of strictures. β -Aminopropionitrile, a potent lathyrogen, has been studied in dogs and was found to be useful in limiting stricture formation [81, 82]. Similarly, penicillamine, which chelates lysine-derived aldehyde groups to prevent collagen cross-linking, was found to limit stricture formation in rats and rabbits

[83, 84]. Colchicine stimulates collagenase activity but was not found to alter wound fibrous response in rats and delayed healing in rabbits [84, 85]. Heparin was found to decrease the incidence of stricture formation in rats, possibly through prevention of submucosal vascular thrombosis [86]. Treatment of rats with interferon gamma and epidermal growth factor also has been shown to decrease the incidence of stricture formation. *N*-Acetylcysteine also was shown in rats to be beneficial in restricting stricture formation [87]. All of these treatments are considered experimental, and their use currently is not supported for human exposures.

Management of Strictures

The development of a cicatricial contracture is the most important consequence for patients who survive the initial crisis of a caustic ingestion with significant injury. These debilitating complications may begin weeks to months after the initial injury and may be classified according to severity to assist in management (Table 2) [88]. Grade 1 strictures are incomplete and noncircumferential. Grade 2 strictures are stringlike, annular, or elastic. Grade 3 strictures are dense, short strictures. Grade 4 strictures are longer than 1 cm and are divided into subtype A, which is superficial and nonprogressive, and subtype B, which is deep, tubular, and progressive.

Various procedures are used for the prevention and treatment of strictures. Estrera and colleagues advocated the use of early intraluminal stenting for immediate and continued prophylactic bougienage of the esophagus. They compared two groups, the

first of which underwent supportive care and dilation as needed, while the second group of patients had early intervention with an intraluminal esophageal stent and radial resection. The second group of patients had esophageal mucosa which appeared more normal when the stent was removed as compared to the first group [42]. Most other authors recommend dilation therapy to normalize the size of the esophageal lumen. Three to 6 weeks after the initial injury, progressively larger bougies are passed over endoscopically placed guidewires for dilation. Fluoroscopy can provide an additional level of safety when strictures are tortuous. The risk of dilation therapy, while small at approximately 1.5% for esophageal strictures in general, is increased when a corrosive ingestion is the cause [89]. Perforation, aspiration, and dysphagia may lead to a host of complications ranging from a general decrease in the quality of life to death.

The severity and extent of the stricture, the age of the patient, and the consideration for long-term risk of esophageal carcinoma contribute to the choice of dilation versus esophageal resection or bypass. Esophageal strictures that are resistant to dilation therapy may indicate surgery. Esophageal bypass leaves the injured esophagus in place and may reroute the gastrointestinal tract using the stomach, jejunum, or colon. Advantages to this technique include a potentially less invasive procedure and avoidance of postvagotomy sequelae. Complications, although rare, can include formation of a mucocele or esophageal abscess that may rupture into the mediastinum [90]. Resection of the esophagus has the same indications as bypass and may be accomplished by thoracotomy or by blunt dissection. Esophagoplasty is a local, in situ operation on the esophagus designed to widen the esophageal lumen. Different authors advocate these various therapies, and no comparison study has been performed to determine which procedure has a superior outcome.

Gastric stenosis may occur at any site in the stomach but is most common in the antrum. Gastrectomy and partial gastrectomies have been advocated in the past. Successful balloon dilation of gastric stenoses also is reported.

Table 2 Stricture description by grade

Grade	Description
1	Incomplete, noncircumferential
2	Stringlike, annular, elastic
3	Dense, short
4A	>1 cm, superficial, nonprogressive
4B	>1 cm, deep, tubular, progressive

Summary

Exposure to caustic substances continues to be a leading source of toxic injury for adults and children worldwide. Although most childhood exposures are unintentional, often resulting in only minor injury, and adult cases are fewer, many deaths occur each year in adults and children owing to the widespread availability of these substances and their inherent dangerous nature. Many patients die either in the acute phase from massive perforation and hemodynamic collapse or in the following few days from a wide variety of complications or multisystem organ failure. These deaths and varied forms of morbidity show the complicated nature of the injury and the comprehensive intensive care these patients require.

It is not sufficient to think only in terms of limiting potentially dangerous sequelae of these ingestions. Rather, we must seek to limit the damage and complications that may result in the death of the patient, before subsequent complications arise. Despite a lack of controlled data supporting a single management plan, many authors advocate a rapid and complete evaluation of the patient with endoscopy as the most important element. Endoscopy is such a useful tool; it should be thought of in terms of which patients *should not* receive endoscopy instead of patients who should. Pediatric patients who are asymptomatic and patients who are so obviously ill that they should be in the operating room are among patients who perhaps should not undergo endoscopy. Aggressive surgical management may be considered for patients with grade 2 or worse injuries because mortality may be decreased, and endoscopic evaluation cannot evaluate the depth of mucosal injuries completely. Steroids and antibiotics may be helpful in reducing the incidence of stricture formation in patients with grade 2B injuries but probably are not likely to help other patients. The most skilled staff available must provide all of this treatment because infection, hemodynamic instability, organ failure, fistulae, and late perforations all contribute to patient morbidity and mortality. Caustic injuries can be deadly to patients and a

formidable challenge for physicians. The astute and aggressive physician can provide the best chances for the injured patient.

Criteria for ICU Admission

1. Evidence of airway injury: stridor, voice changes, drooling
2. Features of sepsis: fever, elevated WBC, vital sign abnormalities
3. Evidence of mediastinitis: septic features with abnormal chest radiograph
4. Metabolic acidosis due to tissue damage or absorption of ingested acid
5. Peritonitis

Criteria for ICU Discharge

1. No evidence of airway compromise
2. No evidence for mediastinitis, peritonitis, or septic complications
3. Patient beginning to tolerate enteral feeds

Key Points

1. A caustic may be an acid, alkali, or other concentrated substance capable of causing injury on contact. These may include a variety of household cleaners, Clinitest tablets, laundry detergent pods, and phenol derivatives.
2. Any location in the aerodigestive tract may be injured after ingestion.
3. Endoscopy is essential to grade the extent of injury and should be performed as soon as possible. Adjunctive diagnostic modalities include radiographs, CT, and contrast esophagoscopy.
4. Corticosteroids may prevent stricture formation in patients with grade 2 esophageal injuries.
5. If viscus perforation is suspected, early surgical consultation is imperative. Surgical treatment may prevent further morbidity and mortality, and options vary depending on the location of injured tissue.

Hydrofluoric acid (HFA) is an inorganic acid used in a variety of industrial and household processes. It commonly is known for its ability to etch glass and silicone leading to widespread use in the semiconductor industry. HFA may be used as a cleaning agent in low-concentration products such as household rust removers and tile grout cleaners. While this chapter primarily discusses hydrofluoric acid, any compound that can release a fluoride ion may cause fluoride toxicity. Other fluoride containing compounds include ammonium bifluoride, which has been used as a wheel-cleaning agent, and sodium fluoride, which has been used as a rodenticide and in dental products.

Biochemistry and Clinical Pharmacology

HFA is a relatively weak acid with a pK_a of 3.8. Although concentrations greater than 50% have corrosive properties, the main toxicity of HFA is related to the fluoride ion. As a weak acid, the unionized HFA molecule can penetrate lipid tissue more easily than stronger acids [1]; once the tissue is penetrated, HFA disassociates releasing a fluoride ion. Fluoride is the most electronegative of all ions and binds strongly to cations such as magnesium and calcium.

calcium, phosphate, and hydroxyapatite. It is proposed that this is similar to what occurs in vivo because hydroxyapatite is present in bone and certain connective tissues. In an animal model, serum calcium was shown to decrease in a 5:1 ratio with the amount of fluoride administered. This ratio is consistent with the formation of fluoroapatite rather than the 2:1 ratio that would be expected if CaF_2 is formed. Regardless of the mechanism, severe hypocalcemia should be anticipated after significant HFA exposure.

Pathophysiology of Toxic Effects**Burns**

HFA burns are classified based on the concentration of the acid [5]. Concentrations greater than 50% cause immediate pain and tissue destruction; concentrations between 20% and 50% may cause burns that are evident within several hours. Burns caused by concentrations less than 20% may not be evident for 24 h. Patients may complain of pain in the absence of visible effects. High-concentration (75%) burns start as classic corrosive injuries. Because HFA is less ionized than stronger acids, it has the capacity to penetrate deeply into tissue. Damage is not limited to superficial levels by tissue coagulation, as is seen with injury from other acids. In further contrast to other acids, the damage to deep tissue is a liquefactive necrosis, and affected bone may develop decalcification [6].

Hypocalcemia

Severe HFA poisoning may cause profound hypocalcemia. Hypocalcemia has been demonstrated consistently in animal models of fluoride toxicity and in reports of human poisoning [7, 8]. The classically accepted mechanism for HFA-induced hypocalcemia is the formation of insoluble calcium fluoride (CaF_2) salts. Other investigators have proposed that the hypocalcemia observed in overdose is from the formation of fluoroapatite, $3(\text{Ca}_3(\text{PO}_4)_2)\text{Ca}(\text{F})_2$ [9]. Fluoroapatite is formed in vitro when fluoride is added to a solution of

Enzyme Inhibition

Fluoride is a potent inhibitor of several enzyme systems, including enzymes involved in oxidative metabolism. Adenylate cyclase is activated by fluorides [10]. Aluminum fluoride has been identified as a molecule that complexes with the enzymes responsible for deactivation of G proteins [10]. Because trace amounts of aluminum are universally present in living systems, it is likely that aluminum fluoride forms when fluoride poisoning occurs. The relative contribution of enzyme toxicity to human fluoride poisoning is unknown.

Other

Other clinical manifestations of fluoride poisoning include hyperkalemia and metabolic acidosis [11].

Clinical Presentation and Life-Threatening Complications**Dermal Injury**

Dermal injury ranging from full-thickness burns to pain without visible injury can occur with HFA exposure [12]. Burns from high-concentration exposures (>50%) are due to the caustic effects and initially are similar to other acid burns. Because HFA tissue penetration is not limited by coagulative necrosis, there may be ongoing

deeper tissue injury even after initial decontamination. Burns caused by low-concentration HFA (20–50%) may not have signs or symptoms for several hours but can progress to full-thickness burns. In a study of 237 patients exposed to HFA concentrations ranging from 6% to 11%, the time to onset of symptoms ranged from less than 30 min in 23% to more than 24 h in 5% of patients. Slightly more than 50% of the patients had redness and swelling, 5% developed blisters, and 23% had only pain [12].

Pulmonary Injury

Hemorrhagic pneumonitis, respiratory failure, and adult respiratory distress syndrome have been reported after inhalation of HFA. These effects are likely due to caustic pulmonary injury [14–16]. Systemic poisoning is a concern after inhalation of hydrogen fluoride. One reported death was associated with high blood fluoride levels [13]. Inhalation also was implicated after an exposure to aluminum bifluoride in a patient who developed systemic toxicity. However, the authors were not able to exclude ingestion of the product [14].

Gastrointestinal Injury

Although HFA is a relatively weak acid, ingestion may cause caustic gastrointestinal injury. Clinical reports suggest, however, that significant caustic gastrointestinal injury is not universal. Accidental ingestion of small amounts of low-concentration products caused gastrointestinal symptoms of abdominal pain, vomiting, and gagging in only 20% of patients [15]. A series of dental fluoride product ingestions also reported a benign course consisting of primarily gastrointestinal upset [16]. Life-threatening fluoride intoxication and death have been reported after HFA ingestion without significant gastrointestinal caustic injury [17, 18]. Although caustic injury can occur, it is not universal, and most importantly the absence of symptoms of caustic injury cannot be used to exclude life-threatening ingestion. Severe rectal

injury and perforation has been reported after rectal administration of HFA [19].

Ocular Injury

Ocular HFA exposure results in a more severe burn than hydrochloric acid at a similar pH [20]. A thorough examination of the eyes must be done in facial splash injuries. Corneal erosions, opacification, and anterior chamber reaction commonly are seen; however, most patients reported have recovered [21, 22]. One case of delayed injury that developed 4 days after exposure has been reported. This patient also recovered [23].

Cardiovascular Toxicity

The most severe effects of acute fluoride toxicity are on the cardiovascular system. The major manifestations of fluoride toxicity on the cardiovascular system are QT prolongation, ventricular dysrhythmias, hypotension, and ventricular fibrillation [11]. The mechanism of this toxicity is likely multifactorial, involving hypocalcemia, hypomagnesemia, enzyme inhibition, acidosis, and hyperkalemia. Most authors consider hypocalcemia the major precipitant of cardiovascular toxicity.

Although most authors consider hypocalcemia the underlying cause of cardiovascular toxicity after fluoride poisoning, one animal model showed that an increase in serum potassium occurs after serum calcium decreases and that cardiac arrest was related temporally to the increase in serum potassium and was not associated with the decrease in serum calcium [7]. As fluoride inhibits the sodium-potassium exchange pump [24], the authors suggested that this poisoning leads to increased functioning of the sodium-calcium exchange pump and resultant intracellular hypercalcemia [7]. Ventricular irritability and dysrhythmias result. This intriguing work suggests that the exact mechanism of fluoride cardiovascular toxicity still is unknown.

Diagnosis

Dermal HFA exposure should be considered in patients who present with severe pain and minimal or no dermal findings after exposure to products known to contain HFA. Patients with dermal exposures that involve more than 5% body surface area at any concentration, or more than 1% body surface area exposure to 50% HFA products, are at risk for hypocalcemia and should be placed on cardiac monitors and have serum calcium and magnesium measurements obtained on arrival at the hospital. The QT interval should be monitored. QT prolongation should be presumed to be due to hypocalcemia.

Patients with symptoms of airway irritation or obstruction
Patients with a significant proportion of body surface area affected
Patients who have ingested concentrated (>50%) hydrofluoric acid

Criteria for ICU Discharge in Hydrofluoric Acid Poisoning

Resolution of pain for >12 h after intra-arterial infusion
Stable serum calcium concentrations in the normal range for 12 h
No need for ongoing monitoring of airway

Treatment

There are no high-quality human studies evaluating treatment for fluoride poisoning. Therefore the treatment recommendations are based on theory, in vitro experiments, animal studies, and observational human data. Given the mechanism of fluoride toxicity, it is reasonable that animal studies may approximate human effects.

Specific Airway and Ventilatory Considerations

Patients with symptoms suggesting upper airway obstruction after inhalation or ingestion of HFA should be intubated. Patients with caustic injury to the oral pharynx or upper airway may require fiber-optic assistance or surgical airway management. Respiratory failure may occur in cases with systemic fluoride poisoning from ingestion, inhalation, and dermal exposure. Respiratory status should be monitored closely in all patients with significant exposure.

Indications for ICU Admission in Hydrofluoric Acid Poisoning

Patients with dermal burns who require intra-arterial infusion of calcium
Patients who develop hypocalcemia after ingestion, inhalation, or dermal exposure

Decontamination

Dermal

In a study of 494 cases of HFA exposures, treatment with only cold water irrigation for 20 min resulted in no patients' developing deep tissue necrosis. Many of these burns were caused by HFA concentrations greater than 40% [25]. When these results are coupled with the ease and safety of irrigation, it is clear that immediate irrigation should be considered standard therapy for HFA exposures (Level of Evidence [LoE]III).

Hexafluorine, which has an affinity for fluoride more than 100 times greater than calcium gluconate, has been advocated for decontamination of HFA exposures. All of 11 patients in a case series treated with hexafluorine following exposure to high-concentration HFA solutions did well. Although these results are promising, the lack of adequate controls in this study prevents definitive conclusions regarding the superiority of hexafluorine over standard decontamination [26].

Enteral

No prospective human trials of therapy for ingestion of fluoride poisoning have been reported. Because of the potentially caustic nature of HFA injury, gastric aspiration or lavage is not

recommended except in cases of massive ingestion where there is a possibility for aspiration of a large amount of HFA from the stomach (LoE III). Charcoal is not recommended. Although human experimental studies are not available, calcium or magnesium solutions (e.g., milk or antacids) administered early may convert fluoride to insoluble salts and prevent systemic absorption [27]. These may be of benefit if administered to patients who can tolerate oral administration (LoE III).

Inhalation

Patients who are exposed to HFA vapors should be removed from the exposure, transported to fresh air, and administered oxygen.

Ocular

Patients with ocular exposure to HFA should have immediate irrigation with water or saline (LoE III). Irrigation with other fluids is of no proven benefit, and animal studies suggest (LoE III) that irrigation with calcium salts may increase injury [20].

Extracorporeal Removal Techniques

Hemodialysis was used to treat one patient who developed hypocalcemia, mild hypotension, and prolongation of the QT interval. The authors reported an excellent response and fluoride clearance of 100 mL/min at a blood flow of 105 mL/min and a clearance of 188 mL/min at a blood flow of 200 mL/min. Nonfluoridated water was used in the dialysate [4]. Although dialysis increases the clearance of fluoride, it is unlikely that severely poisoned patients would tolerate dialysis.

Antidotes

Dermal

Classic therapies for HFA burns include magnesium oxide, ice water irrigation, and ammonium salts. Animal studies have shown, however, that calcium provides superior neutralization of fluoride ions [28]. Human case series also suggest that calcium provides outcomes superior to those of other therapies (LoE III) [12]. I recommend a

stepwise approach using progressively more invasive therapies to treat dermal injuries caused by low-concentration ($\leq 50\%$) HFA exposures. After irrigation, patients should be treated with topical 2.3–2.5% calcium gluconate gel [12]. The gel is formulated by the addition of 10 mL of 10% calcium gluconate solution to methylcellulose (preferred) or 30 mL of water-soluble lubricant, applied liberally to the affected areas and allowed to remain in place for 15 min after resolution of the pain and for a minimum of 30 min [29]. The gel is reapplied immediately if symptoms recur. The treatment is continued every 4–6 h for the next several days. Burns involving the hands may be treated by placing the gel in tight-fitting latex gloves. This approach has been associated with resolution of symptoms in at least two large series [12, 30]. Topical therapy usually is sufficient for exposure to HFA concentrations of less than 20% (LoE III). The role of topical treatment for more severe exposures is not as well defined, but it was used in a patient who was completely immersed in HFA and survived [31]. Given the low toxicity of topical calcium gel, I recommend its use as an adjunct therapy to systemic calcium administration for higher concentration exposures.

Injection of HFA skin burns with calcium to bind the fluoride ion has been recommended for more than 60 years [32]. Current recommendation is injection of 0.3–0.5 mL/cm² of 10% calcium gluconate with a 27G to 30G needle (LoE III) [33]. Local calcium injection is most useful in cases in which topical therapy is not effective in providing symptomatic relief and regional perfusion therapy is not possible (i.e., head, face, trunk, perineum) [33]. Because the volume that can be injected into the digits is limited to 0.3–0.5 mL/cm², this therapy is considered by many to be of limited utility if the digits are involved. If the fingers or toes are involved and do not improve with topical therapy, it is reasonable to move directly to regional perfusion techniques. Calcium chloride should not be used because it may cause local tissue necrosis [33].

Regional intravenous perfusion using Bier's technique has been advocated as an alternative to intra-arterial therapy for burns to the extremities (LoE III). This treatment is well described for the

upper extremity and has been used for the lower extremity [34]. The technique involves placement of a small-gauge intravenous catheter in the affected extremity. The extremity is exsanguinated using elevation and a tourniquet is inflated to 100 mmHg above the systolic blood pressure. After inflation, calcium gluconate diluted in normal saline is infused over a few minutes. While a range of doses have been reported, the largest published case series used 10 mL of a 10% solution diluted with 30–40 mL of normal saline [35]. No patient noted symptoms suggesting hypercalcemia [34]. The tourniquet is deflated gradually over 5 min after 15–25 min. Relief is usually prompt, and failure to alleviate symptoms with one treatment may be an indication for intra-arterial therapy [34], although other investigators advocate repeating the Bier technique [35]. Patients often require parenteral analgesia to tolerate the tourniquet. Addition but is not recommended. Although it provides immediate relief of symptoms, the loss of pain sensation removes the best marker of tissue toxicity.

Patients with persistent pain in an extremity after regional intravenous infusion may be treated with intra-arterial calcium infusion (LoE III). Patients usually report prompt relief of pain, and tissue loss usually is avoided [36]. For burns involving the foot or leg, the femoral artery is cannulated with a 5 F arterial catheter. The brachial artery is cannulated for hand burns involving more than the thumb and index finger, whereas burns involving only these fingers may be treated by infusion through a 20G radial artery catheter. To assist the infusion, the catheter is directed distally rather than proximally. Although some authors advocate an arteriogram to verify that the vessel is patent and supplies the affected area, confirmation that the catheter is generating an appropriate waveform every hour seems to be sufficient. Several infusion protocols have been reported. The largest series used 10 mL of 10% calcium gluconate diluted with 40 mL of normal saline and infused over 4 h [36]. The addition of 500 U of heparin to the infusion mixture may decrease the incidence of clotting. After the infusion, the line is flushed with an

additional 10 mL of saline over 15 min, then flushed hourly with heparinized saline. If tenderness or pain is present after 4 h of observation, the infusion is repeated. Using this protocol, the average number of infusions was 4.1, and no patient had significant tissue loss. Several patients required systemic magnesium replacement, and the authors recommended checking serum magnesium levels 1 h after the completion of the infusion [37].

Adjunctive therapies for HFA burns involving the hands or feet have included fasciotomy to facilitate the injection of larger volumes of calcium gluconate into the digits (LoE III) and removal of the nails when there is substantial subungual involvement (LoE III) [38]. Use of the stepwise approach should allow treatment of digital injuries without resorting to either of these steps.

Pulmonary

Currently, no therapies other than standard supportive care can be recommended for pulmonary irritant exposure. Although some authors have advocated early steroid administration, this is not supported by any controlled data, and there is a theoretical potential to increase the risk of infection. Thirteen patients with mild to moderate pulmonary irritation following HF inhalation were treated with 4 mL of nebulized 2.5% calcium gluconate [39]. No patient developed significant pulmonary toxicity or seemed to have any adverse effects. Although these results are uncontrolled and the symptoms were not severe, nebulized calcium gluconate is a reasonable intervention for symptomatic patients with mild to moderate pulmonary irritation after HF inhalation.

Systemic

Few experimental data are available regarding the specific treatment of systemic toxicity from HFA. Most studies instead have looked at sodium fluoride. Animal studies have resulted in variable results regarding the administration of calcium for the treatment of acute fluoride toxicity. Strubelt and colleagues [40] reported that calcium

increases the lethal fluoride dose by 17% in a rat model. Although the results were not statistically significant, the sample size was small and did not exclude a clinically significant effect. Simultaneous administration systemic administration of calcium chloride and sodium fluoride in a 1:1 molar ratio improved survival in a mouse model of fluoride toxicity. There was no change in survival when animals were treated with magnesium sulfate [41].

As noted earlier in the section on clinical presentation, cardiac arrest in fluoride-poisoned dogs was related temporally more closely to an increase in serum potassium than to a decrease in serum calcium. Calcium chloride, epinephrine, glucose/insulin, and lidocaine did not improve survival, whereas simultaneous administration of quinidine with calcium did. The authors hypothesized that quinidine prevents potassium efflux from fluoride-poisoned cells via calcium-mediated potassium channels and prevents fluoride toxicity. They also suggested that administration of calcium as treatment of hyperkalemia may elevate intracellular calcium levels and increase fluoride toxicity [7]. The clinical utility of quinidine in the treatment of human poisoning has not been evaluated. Because of the possibility of further prolongation of the already lengthened QT interval by quinidine, its use cannot be recommended routinely.

Infusion of isotonic sodium bicarbonate in doses to maintain arterial pH in the 7.45–7.50 range has been shown to improve survival in a rat model of systemic fluoride poisoning [40]. Acetazolamide administration further increased survival time and total fluoride dose. The terminal ratio of fluoride in cardiac tissue to serum was lower in treated animals. The authors hypothesized that alkalosis changes the distribution of fluoride and increases renal fluoride clearance. Serum alkalinization is a reasonable adjunct to calcium for treatment of severe systemic fluoride poisoning (LoE III).

Human cases documenting survival of cardiac arrest after severe fluoride toxicity are rare. The administration of large doses of calcium has been associated with survival in several cases,

however [8, 14]. In one report, a patient presented twice after ingesting an HFA-containing rust removal agent [42]. After the initial presentation, she developed hypocalcemia and subsequently had a cardiac arrest. She was treated with a total of 111.6 mEq of calcium and 16 mEq of magnesium during her resuscitation and recovered. After discharge from a psychiatric facility, the patient presented again after ingesting what was reported to be the same amount of the same rust removal agent. This time she was treated with prophylactic calcium and magnesium (a total of 65.1 mEq calcium and 32 mEq of magnesium) and recovered uneventfully. Although only suggestive, this case suggests that early administration of calcium may prevent or attenuate the severe cardiac effects that occur after large HFA exposures and is a reasonable intervention (LoE III).

Excision has been advocated after survival of one patient who went into cardiac arrest five times while receiving vigorous calcium replacement, then stabilized after excision of the burn site [43]. Although this case is interesting, it is not clear that the tissue excision contributed to the patient's survival. Because of the potential to cause serious injury during the excision, this treatment should be considered only for the most critically ill patients who are not responding to aggressive calcium repletion.

No treatment for systemic fluoride poisoning has been shown to improve survival in systematic human studies. In my opinion, aggressive decontamination and care of dermal exposures, supportive care with an emphasis on airway management, and early administration of large doses of intravenous calcium should be considered standard of care. McIvor and colleagues [7] suggested that late administration of calcium may be deleterious but still recommended early administration of calcium. Administration of an isotonic sodium bicarbonate infusion to maintain a mild systemic alkalosis (pH 7.45–7.50) may decrease cardiac fluoride concentrations, may increase fluoride clearance, and is of low toxicity. Moderate or severe systemic alkalosis (pH >7.50) may cause ionized calcium concentrations to fall, however, worsening systemic hypocalcemia.

Special Populations

Pediatric Patients

Pediatric patients are presumed to be at increased risk of toxicity from dermal exposure because they have high surface area-to-volume ratios such that a given percent body surface area exposure results in higher total body exposure.

Pregnant and Elderly Patients

There are no available data on the treatment of pregnant or elderly patients exposed to HFA. Standard therapy is recommended.

Common Errors in Hydrofluoric Acid Poisoning

Failure to appreciate that systemic toxicity can occur after dermal exposure

Failure to appreciate that systemic toxicity can occur after ingestion even in the absence of oral or gastrointestinal symptoms

Key Points in Hydrofluoric Acid Poisoning

1. Irrigate affected area immediately with water.
2. Dermal exposures should be treated initially with topical calcium; patients who have persistent pain should receive local injection or regional perfusion with calcium.
3. Systemic poisoning may occur after ingestion, inhalation, or dermal exposure and may result in rapid cardiovascular collapse.
4. Systemic poisoning should be treated with large doses of intravenous calcium.

Ciguatera poisoning is a multisystem illness caused by the ingestion of fish containing neurotoxins, commonly known as ciguatoxins, though this includes ciguatoxins, maitotoxin, and gambierol, all from the same dinoflagellate source. Ciguatera was known in antiquity, although the term “ciguatera” dates from the seventeenth century Spanish colonization of Cuba [1]. James Cook described an illness producing gastrointestinal (GI) and neurological symptoms typical of ciguatera poisoning while captaining HMS Resolution in 1774 near the Pacific Island of Vanuatu [2]. Although mortality related to ciguatera poisoning is low, symptoms can be disabling and, in a minority of cases, persistent.

Ciguatoxins are produced by microalgae living on the sea floor, which grow through photosynthesis. The epiphytic dinoflagellate, *Gambierdiscus toxicus* produces gambiertoxins, which undergo biotransformation into ciguatoxins as they move through the food chain [3–5]. Herbivorous fish and to a lesser extent mollusks and crustacea ingest microalgae and are in turn eaten by carnivorous fish [6]. Biotransformation through the food chain preserves lipophilic properties but transforms ciguatoxins into more oxidized, polar, and toxic molecules, although overall lipophilic properties are maintained [5]. Carnivorous fish are the main source of ciguatoxin exposure for humans; however, herbaceous fish can also serve as human vectors [7]. Maitotoxin, being a more hydrophilic polyether,

Fig. 1 Polycyclic structure of Pacific ciguatoxin-1

is not concentrated up the food chain and is restricted to herbivorous fish.

Ciguatera poisoning, the term covering poisoning by this group of toxins (ciguatoxins, maitotoxin, and gambierol) is the most common marine poisoning and is endemic in tropical and subtropical areas between the latitudes of 10° north and 10° south, particularly in the Caribbean and Indo-Pacific regions [8, 9]. This is consistent with the distribution of warm-water bottom-dwelling reef fish associated with ciguatera poisoning. Over 500 species of fish have been associated with ciguatera poisoning in humans; however, the most common are Spanish mackerel, cod, moray eels, barracuda, red bass, snapper, sea bass, groupers, coral trout, and tuna [9]. Increasingly mobile human populations, transportation of fish to global markets, and climate change mean ciguatera poisoning is increasingly encountered in non-endemic regions [8, 10–12]. Fish containing ciguatoxins do not appear, smell, or taste unusual. Ciguatera is not heat-labile, and poisoning can occur even after frying, baking, boiling, or stewing fish [7].

Ciguatera accounts for over half of all fish-borne cases of poisoning reported in the United States. The most commonly affected areas include Florida and Hawaii, with a peak incidence between May and August [13, 14]. Reported incidences vary from less than 0.1% of populations in Florida and Queensland, Australia, to greater than 50% of populations in South Pacific and Caribbean Islands [15]. Ciguatera poisoning produces a

significant socioeconomic burden in many South Pacific islands, where seafood is a major dietary component [16]. Global estimates range widely from 20,000 to 500,000 cases annually [15–17]. Difficulty in diagnosis, reluctance to report cases due to the belief that there is no effective treatment for symptoms, and lack of physician familiarity with the disease in non-endemic regions lead to a likely gross underreporting of the true incidence of the disease [9, 16–18].

Biochemistry and Clinical Pharmacology

Ciguatoxins are a group of moderately large (~1100 Da), lipophilic, colorless, odorless, highly oxygenated cyclic polyethers [19, 20]. Ciguatoxins are stable in mildly acidic and basic environments. The compounds are heat-stable, so cooking or freezing does not destroy them [5]. More than 40 ciguatoxins have been identified; their relative abundance varies with geographical location and may account for regional variation in the spectrum of clinical effects related to ciguatera poisoning [21]. Pacific ciguatoxin-1 (Fig. 1) measured in an intraperitoneal mouse assay is ten times more potent than Caribbean ciguatoxin-1; neurological features predominate in cases of ciguatera poisoning in the Pacific, while gastrointestinal symptoms are more prominent in Caribbean cases

[17]. Multiple different ciguatoxins may exist in the flesh of the same fish, with the content dependent on geographical location, species, and degree of exposure to toxic microalgae [4]. Ciguatoxins are secreted in breast milk and cross the placenta; however, little else is known about the pharmacokinetics of ciguatoxin [22–24]. Gambierol is also a lipophilic polyether, stable, concentrated up the food chain. Maitotoxin is a larger molecule, a hydrophilic polyether, less stable. Gambierol and maitotoxin have different target sites to the ciguatoxins.

Pathophysiology of Toxic Effects

Ciguatoxins are among the most potent sodium channel activators known; ingestion of 0.1 µg of Pacific ciguatoxin-1 can produce significant clinical toxicity [25, 26]. Ciguatoxins bind to site “5” on the alpha subunit of neuronal voltage-gated sodium channels, opening the channels at picomolar and nanomolar concentrations [27, 28]. Cell membrane depolarization leads to tetrodotoxin-sensitive sodium channels firing spontaneously. Increased neuronal sodium permeability increases intracellular calcium influx and axonal swelling, subsequently slowing both sensory and motor nerve conduction velocities [29–33]. Sural nerve biopsies in patients with significant neurological symptoms have shown edema of Schwann cells and myelin fibers. Nerve conduction studies have demonstrated evidence of a polyneuropathy with reduction of sensory and motor conduction velocities and an increase in absolute and relative refractory periods, particularly in sensory small fiber neurons [34, 35]. Increases in intracellular calcium concentration disrupt intestinal cell ion-exchange mechanisms, producing fluid secretion and diarrhea [35].

A large number of in vitro animal and human studies suggest ciguatoxins possess other cellular effects, which may contribute to the spectrum of observed clinical effects. These include stimulation of neurotransmitter release from motor nerve terminals, induction of membrane

potential oscillations in dorsal root ganglion cells, antagonism of voltage-gated potassium channels, alteration in function of C-polymodal nociceptors, and nitric oxide-mediated release of inflammatory cytokines capable of stimulating N-methyl-D-aspartate (NMDA) receptors [36–39]. Gene expression studies and measurement of inflammatory markers post-ciguatera exposure in patients with persisting symptoms suggest disruption of innate and adaptive immune responses and the development of a chronic neuro-protective anti-inflammatory response [40–42].

Maitotoxin targets several different ion channels, but especially calcium channels, causing increased calcium influx into cells, though also affecting some sodium channels. This results in neurotransmitter secretion and contraction of excitable tissues, among other effects, though the clinical correlation remains uncertain. Less is known about gambierol, though it appears to target voltage-gated potassium channels, blocking potassium efflux [43].

Clinical Presentation and Life-Threatening Complications

The time of onset of clinical effects following ingestion of fish containing ciguatoxins varies, with documented cases reporting symptom onset between 1 and 48 h, although in one large series, symptoms occurred within 12 h in 75% and 24 h in 96% of cases [7, 44–46]. Characteristically, an acute gastrointestinal illness is followed by a variable array of neurological symptoms [7, 45–52]. Less commonly cardiovascular, neuropsychiatric, and other generalized symptoms occur. Clinical manifestations of ciguatera poisoning are summarized in Table 1.

Gastrointestinal symptoms usually occur within 12 h of ingestion and may be severe, resulting in fluid depletion requiring intravenous replacement. They may be accompanied by diaphoresis and headache. Diarrhea appears to be the most commonly reported gastrointestinal symptom with one large case series of over

Table 1 Clinical manifestations of ciguatera poisoning (life-threatening complications in bold)

Gastrointestinal	Neurological	Cardiovascular	Other
Abdominal pain Nausea and vomiting Watery diarrhea Dehydration	Seizures Coma Paraesthesias Cold allodynia Peripheral dysesthesias Headache Sensation of loose or painful teeth Numbness of tongue, lips, perioral area Weakness Ataxia Vertigo Visual disturbance (scotoma, transient blindness, blurred vision)	Bradycardia Hypotension (may just be orthostatic hypotension in many cases)	Respiratory failure Diaphoresis Hyperthermia Hypothermia Metallic taste Singultus Myalgias Arthralgias Pruritus Rash on palms and soles Depression Fatigue Dysuria Proctalgia Testicular pain Dyspareunia (male and female)

3,000 patients reporting a 70% incidence [7]. Abdominal pain, nausea, vomiting, and diarrhea typically resolve within 24 h but may last up to 4 days.

A plethora of neurological symptoms have been reported in association with ciguatera poisoning, typically appearing within 24 h of exposure but sometimes delayed up to 72 h [7, 45–52]. Common symptoms include distal limb and perioral paraesthesias and cold allodynia; these have been reported present in 90% of patients in one series [7]. Cold allodynia is often described as temperature reversal; however, it is more accurately described as dysesthesia (an unpleasant sensation) resulting from exposure to cold [49, 53]. If present in the context of fish ingestion and gastrointestinal symptoms, cold allodynia is highly specific for ciguatera poisoning. Cold allodynia can be significantly disabling, preventing patients from washing with cold water or even walking across tiled floors [53]. In one prospective study, 80% of patients had abnormal temperature sensation and 50% abnormal pain and vibration perception [54]. The dysesthesias have frequently been described as tingling or “electric shock” type sensations. Light touch sensation may

also be reduced [54]. Tendon areflexia, dysphagia, and cerebellar dysfunction can occur but are rare [54]. Coma has also been reported [7, 55].

Cardiovascular dysfunction has been reported early in the course of severe cases, manifesting most commonly as bradycardia and hypotension, most likely orthostatic in nature in most patients [56–58]. Nonspecific ECG abnormalities have also been reported, but the incidence of cardiovascular features of poisoning is relatively rare [45–52].

Myalgia and arthralgia occur in up to 80% of cases [7]. Dental pain, a sensation of loose teeth, a metallic taste, rash (typically on the palms and soles), pruritus, fatigue, and depression are less common [7, 60, 61]. Fever or mild hypothermia can occur [44, 62]. Proctalgia, dysuria, testicular pain, pain with penile erection and ejaculation, and dyspareunia have been reported [2, 63–66]. There are reports of male to female and female to male sexual transmission of ciguatera-related symptoms [67].

The pattern and severity of symptoms can vary between individuals who have eaten the same fish, which may reflect the presence of a multitude of different ciguatoxins present within one fish [8]. Severity of symptoms appears to be related to the

size of the fish and the parts eaten; more severe toxicity occurs following ingestion of the head or organs [47]. However, some case series suggest that there is no clear dose-response relationship, with variability between amount of fish reportedly ingested and subsequent severity and duration of symptoms between individuals [46, 62, 68]. Although the most common symptoms are paresthesias, cold allodynia, myalgias/arthralgias, and diarrhea, their pattern is often complex and highly variable with some patients not experiencing a number of these common symptoms, just a few, or multiple different ones [69].

Although GI symptoms normally resolve over a few days, neurological symptoms, cardiovascular symptoms, pruritus, myalgias, arthralgias, singultus, headache, depression, and fatigue have been reported to last months to several years in a up to 5% of cases [9, 44, 47, 69, 70].

Predicting the course of the disease based on the severity of the initial presentation is unreliable; some patients with relatively minor symptoms go on to develop troubling chronic symptoms, while others with severe poisoning requiring critical care interventions are asymptomatic within weeks [68]. There are also regional variations in clinical patterns of toxicity. Gastrointestinal symptoms predominate acutely in the Caribbean, while neurological symptoms are more commonly seen early in the course of poisoning in the Indo-Pacific regions [5].

Sensitization to ciguatoxins has been reported. Apparent recurrence of symptoms years after the initial exposure has been documented following ingestion of fish (including fish not normally associated with ciguatoxins), alcohol, and other foods including nuts, chocolate, mushrooms, and seeds [6, 9, 67]. Postulated mechanisms of sensitization include long-term storage of ciguatoxins in adipose tissue or an underlying immunological mechanism [9, 70]. There have also been reports of ethanol and caffeine exacerbating symptoms during the initial few days of the disease [26, 72, 73]. Evidence from the South Pacific region where seafood is a major dietary component suggests that repeat ciguatoxin exposure may lead to more severe symptoms

compared to the initial episode of poisoning [7, 65].

Life-threatening clinical toxicity is rare but may occur in cases of significant dehydration, cardiovascular dysfunction, and respiratory failure or when seizures occur and adequate supportive care is not able to be provided. There are rare reports of patients with rapid progression of respiratory distress and development of coma. Deaths have been reported outside of the United States, but the overall mortality rate is much less than 0.5% [58, 64].

Diagnosis

Ciguatera poisoning is a clinical diagnosis, based on the history of ingestion of reef fish, the occurrence of typical symptoms including gastrointestinal and neurological features, and the exclusion of other diagnoses. There is no clinically useful qualitative or quantitative investigation available in human biological fluid. Cases occurring distant to tropical and subtropical areas may be undiagnosed because of the rarity of cases and lack of local physician knowledge or awareness of ciguatera poisoning. Ciguatera poisoning shares a number of clinical features with scombroid poisoning, neurotoxic shellfish poisoning, bacterial sepsis, and polyneuropathies such as multiple sclerosis. A diagnosis of ciguatera poisoning is more likely to be made if multiple patients present with typical symptoms following ingestion of fish.

Ciguatoxin can be detected within fish flesh using high-pressure liquid chromatography–tandem mass spectrometry [74] or a number of in vivo and in vitro animal tissue assays [15]. A history of ingestion of fish possibly containing ciguatoxin, the development of typical clinical features of poisoning, and detection of ciguatoxin in fish remnants is currently the diagnostic gold standard. However, these assays are rarely available for physicians and are not completed in a time frame likely to influence clinical management. Additionally, analytical assays suffer in terms of sensitivity because of

the heterogeneous nature of ciguatoxins found in any one fish. Traditional methods of testing fish for the presence of ciguatera in tropical areas include smearing the fluid from fish organs across one's gums and waiting for paresthesia to develop [75].

Treatment

Airway and Ventilation

In rare cases where coma occurs, endotracheal intubation and ventilation may be indicated for airway protection. Artificial ventilation may be required in rare cases of respiratory failure.

Circulation

Bradycardia usually responds to atropine (level of evidence [LOE II]) [56–58]. Hypotension should initially be treated with intravenous fluid and correction of bradycardia (LOE III) [58, 76]. In rare cases, inotropic support may be required [58].

Decontamination

The potential benefit of oral-activated charcoal administration has not been studied in ciguatera poisoning. Theoretically, activated charcoal may reduce the severity of poisoning if administered to a conscious patient with a protected airway within an hour of ingestion; however, early onset of gastrointestinal symptoms of toxicity may limit charcoal administration (LOE III). Activated charcoal has not been shown to alter the outcome in ciguatera poisoned patients.

Extracorporeal Techniques

Ciguatoxins are large, extremely lipophilic, and have a wide volume of distribution. Extracorporeal elimination techniques are not useful in treating ciguatera poisoning (LOE III).

Specific Treatments

Non-antidotal

Management of ciguatera poisoning is primarily supportive. Dehydration secondary to vomiting and diarrhea should be corrected with administration of intravenous crystalloids. Electrolyte disturbances should be treated in a standard manner. Patients may benefit from administration of an antiemetic to treat nausea and vomiting or an antihistamine to treat pruritus. Neuropathic pain associated with ciguatera poisoning can be difficult to treat. Case reports and small case series suggest possible benefit from a number of drugs including amitriptyline for pruritus, headaches, and paresthesias [77, 78], nifedipine for headaches [78], and fluoxetine for chronic fatigue (LOE III) [79]. Gabapentin and pregabalin have been reported as effective treatments for ciguatera-related dysesthesias (LOE III) [80, 81]. Patients should be warned to avoid consumption of alcohol, caffeine, or fish if these exacerbate their symptoms. Traditional herbal medications and remedies are commonly used in the South Pacific region to treat ciguatera poisoning, with over ninety different plant species listed as potentially useful in New Caledonia alone [82, 83]. However, there are no studies demonstrating their effectiveness or safety [76].

Antidotal

Mannitol is the most widely studied specific treatment for ciguatera poisoning. Mannitol reverses in vitro effects of ciguatoxin, including neuronal cell edema [84]. Mannitol was originally used to treat two patients in the South Pacific with cerebral edema associated with ciguatera poisoning. The neurological effects resolved completely in both patients. A further 22 patients were treated with complete resolution of neurological effects in 17 [85]. Mannitol was subsequently used widely, and case reports and case series reported beneficial effects in treatment of neuropathic pain and other symptoms when administered up to several weeks postexposure [70, 86–88]. Gastrointestinal symptoms do not appear to resolve with mannitol administration. A randomised non-blinded trial of 65 patients in French Polynesia demonstrated a statistically significant reduction in symptoms in the group ($n = 34$) receiving a mannitol infusion

compared to the supportive care ($n = 29$) group [89]. A blinded, randomized controlled trial of 50 patients receiving either mannitol ($n = 25$) or a normal saline infusion ($n = 25$) showed an improvement in clinical features of poisoning in both groups [54]. Mannitol was not superior to normal saline in this study; however, 25% of the patients in the mannitol group were treated greater than 69 h postexposure, while other reports had suggested mannitol was most beneficial if administered within 48–72 [70, 85–88]. A subgroup analysis of patients treated within 24 h of ingestion did not demonstrate a beneficial effect of mannitol over normal saline but suffered from small patient numbers. True blinding in this study has also been questioned with 84% of patients receiving mannitol reporting pain at the infusion site, compared to 36% in the normal saline group [54, 68]. Mannitol may reduce edema within neurons via an osmotic effect, inhibit the ciguatoxin-induced opening of neuronal sodium channels, and increase the dissociation of ciguatoxin from its binding site [30, 90]. It may cause fluid shifts and hypotension and so must be used with caution in significantly dehydrated or hypotensive patients. Mannitol may ameliorate the non-gastrointestinal clinical effects of ciguatera poisoning and is more likely to be beneficial if administered within 48–72 h of exposure (LOE II-3). Based on the available evidence, mannitol should be considered as an intervention in any patient presenting with significant non-gastrointestinal effects, within 48 h of ciguatera exposure. Mannitol must not be administered to shocked or volume-depleted patients.

Other antidotes have been developed but require further study before potential human use can be attempted or recommended. Brevenal is a naturally occurring cyclic polyether molecule that has been artificially synthesized and acts as an antagonist of brevetoxins [91]. Brevetoxins share properties with ciguatoxins and act at the same voltage-gated sodium channel. In vitro studies have demonstrated the ability of brevenal to antagonize the effects of brevetoxin. However, further study is required to evaluate the possible utility of this molecule in treating ciguatera poisoning [92, 93]. Monoclonal antibodies

synthesized to neutralize ciguatoxin CTX3C have been shown to neutralize CTX3C in vitro and in vivo in a mouse model [94], though the large number of identified ciguatoxins present in any one fish may limit the utility of this approach.

Indications for ICU Admission in Ciguatera

Poisoning

- Persistent hypotension not responsive to fluid
- Persistent bradycardia not responsive to atropine
- Respiratory failure requiring support
- Coma requiring intubation for airway protection
- Seizure activity requiring supportive care
- Severe electrolyte disturbance

Criteria for ICU Discharge in Ciguatera

Poisoning

- Normal vital signs
- Not requiring inotropic support
- Normalizing electrolytes

Special Populations

Infants and Elderly Patients

Because of the possibility of dehydration, care should be taken to ensure adequate fluid balance and electrolyte correction in infants and elderly patients before treatment with mannitol.

Pregnant Patients

Pregnant patients should be warned that there are some reports of transient neurologic abnormalities in infants born to mothers who have had ciguatera fish poisoning [95]. There are other reports of spontaneous abortion and premature labor [50]. Nursing mothers with ciguatera poisoning should be advised against breast-feeding because there are some reports of diarrheal illness in infants breast-fed by ciguatoxic mothers [50].

Other Patients

Patients who have been affected previously by ciguatera fish poisoning may have more severe symptoms on reexposure [7].

Key Points in Ciguatera Poisoning

1. Ciguatera fish poisoning is a worldwide phenomenon.
2. Poisoning occurs after the ingestion of fish containing ciguatoxin, which is derived from dinoflagellates.
3. Initial symptoms are gastrointestinal, with neurologic symptoms following.
4. Neurologic symptoms may be delayed in onset and prolonged.
5. Life-threatening features are rare but may include coma, respiratory insufficiency, seizure, bradycardia, and hypotension.
6. Management is essentially supportive, although mannitol may benefit some patients.

Acknowledgments The author would like to acknowledge the work of Dr. Fergus Kerr who initially wrote this chapter.

Jellyfish

Jellyfish belong to the phylum Cnidaria (Greek derived from ‘nettle’) and are mostly free-swimming marine animals that may have an umbrella-shaped bell with varying length tentacles. The pulsations of the bell are relied on as their mode of locomotion, while the tentacles are typically used for capturing prey. Jellyfish have a worldwide distribution, occupying every ocean and some freshwater lakes. The phylum is comprised of several distinct life forms and four important classes of jellyfish: Cubozoa, Hydrozoa, Anthozoa, and Scyphozoa. The defining feature of Cnidaria is the cnidocyte, and the tentacles of most jellyfish are lined with thousands of them (Figs. 1 and 2). Each cnidocyte contains a harpoon-like organelle known as a cnida or cnidocyst. On the external surface of the cnidocyte is a cnidocil which, when activated by pressure, osmotic, or chemical changes, acts like a trigger, releasing the previously coiled harpoon. Once forcefully expelled, a process that takes microseconds, the harpoon is capable of penetrating human tissue. Venom is forced out of the cnidocyte under pressure through the epidermis and upper dermis and, particularly if dermal capillaries are inoculated directly, can enter the systemic circulation. It is sometimes stated that these may be inadvertently accelerated by the rubbing or shaking of a startled human victim, but there is no reliable evidence that this actually occurs.

The Cubozoa, or box jellyfish, are not considered true jellyfish, but represent the phylum’s most dangerous species (*Chironex fleckeri*, *Malo kingi*, and *Carukia barnesi*). This class contains cube-shaped, four-cornered jellyfish that are ordained with up to 15 tentacles per corner. *Chironex fleckeri* (roughly translated from Greek as the “assassin’s hand”) is commonly referred to as the big box jellyfish. This species of jellyfish is endemic to Australia, particularly off the Northern Coast [1]. As an adult the *C. fleckeri* has a bell the measures up to 38 cm with tentacles that may reach 3 m in length. The much smaller *Carukia barnesi* (family *Carybdeid*), aka “Irukandji jellyfish,” which as an adult, has a bell that measures a

Fig. 1 Nematocyst before discharge (From Ref. [133], p. 1454)

Fig. 2 Nematocyst after discharge (From Ref. [133], p. 1455)

mere 2.5 cm in diameter and tentacles the reach up to 100 cm from the bell. Given its small size, this jellyfish is not only elusive to the unsuspecting swimmer, but historically proved elusive to investigators. Hugo Flecker originated the term “Irukandji syndrome” in 1952 which is used to describe a set of clinical manifestations associated with, though not specific to, the sting of *Carukia barnesi* [2]. While its range was initially thought to be fairly wide, the “Irukandji jellyfish” is probably limited to Queensland waters [2] and the assumption of a wider distribution may be from envenomations from other members of the carybdeid family (i.e., *Carukia shinju*).

Interestingly, in 1964 a volunteer lifesaver by the name of Barnes cemented his place in history when he captured a specimen of a previously unnamed jellyfish and intentionally stung himself, and his own son, who were treated on site and survived. The offending jellyfish was named *Carukia barnesi*, sometimes referred to as the “Barnes’ jellyfish” [3]. Despite the lore around this species of box jellyfish, there has only been one death worldwide attributed to its sting.

Malo kingi (formerly *Chiropsalmus quadrigatus*), a species of box jellyfish, is also found in the Indo-Pacific region, particularly off the Philippian coast. This species has a bell measuring 7 cm in diameter and may have upwards of 60 tentacles, reaching as long as 3 m.

The Hydrozoa class contains two important species of jellyfish (*Physalia physalis* “Portuguese Man O’War” and *Physalia utriculus* “Pacific Man O’War”) and several species of medically important organisms (discussed below). An interesting feature of these two jellyfish is that rather than being a single self-sustaining organism, the creatures are a mass of hydroids living as a single colony. The floating colony is easily recognized by the characteristic sail, usually blue, which floats above the water’s surface. These hydrozoa can be found anywhere on the open ocean, but are more commonly found in tropical/subtropical regions of the Atlantic, Indian, and Pacific Oceans.

Scyphozoa, or true jellyfish, are home to a few medically important jellyfish such as *Cyanea*

capillata (lion’s mane jellyfish), *Chrysaora quinquecirrha* (sea nettle), and *Linuche unguiculata* whose larvae may cause a condition known as sea bather’s eruption. *Cyanea capillata* is considered one of the longest animals in the world, its combined length of the tentacles reaching as long as 63 m. Both *Cyanea* and *Chrysaora* spp. are found in tropical and temperate waters including, in particular, the Chesapeake Bay.

Pharmacology

Cnidaria venom is a complex, proteinaceous mixture capable of causing dermatonecrosis, myonecrosis, and cardiotoxicity and is species dependent.

Chironex fleckeri is considered one of the most venomous creatures in the world [4]. In 1959, Southcott and Kingston described a triad of basic toxicologic manifestations, cardio-respiratory failure, dermatonecrosis, and hemolysis. Over the last five decades, further in vitro and in vivo animal research has provided some insight into the reasons why certain clinical features are observed. First, a biphasic blood pressure response (initial hypertension, then hypotension) is often observed. An initial vasoconstrictive phase is followed by subsequent hypotension, likely from reduction in coronary blood flow, heart rate and contractility, arrhythmias, and baroreceptor stimulation [5]. Furthermore, there is an irreversible increase in intracellular calcium in rat myocytes which is speculated to correlate to atrio-ventricular block and systolic dysfunction in human cardiac tissue. This ion influx may result from pore-forming properties from two of *Chironex fleckeri*’s most abundant venom components, CfTX-1 and 2 [6].

The pain following envenomation may arise from modulation of nonselective cation channels expressed in nociceptive neurons [7]. There at least two myotoxins in the venom, both of which are capable of inducing skeletal muscle contractions in rat models [8]. Hemolytic effect, which may be a surrogate marker for venom-induced

cell-permeability and ion pore formation, is a rarely reported finding in humans [4].

Carukia barnesi is capable of inducing “Irukandji syndrome,” a series of signs and symptoms common in excess catecholamine states. Crude venom extract has been shown to cause the release of catecholamines in both in vitro and in vivo experiments [9]. The catecholamine release is likely, at least in part, from a prejunctional neuronal sodium channel activator which may be attenuated in the presence of tetrodotoxin or conotoxin. There is also, however, concentration-dependent contraction in rat mesenteric arteries that is not inhibited by tetrodotoxin. In isolated, human right atrial muscle, exposure to crude venom extract initially reduced contractile force, but was followed by a more sustained force of contraction. Sustained tachycardia and pulmonary hypertension has been demonstrated in in vivo piglet experiments where elevations of circulating noradrenaline and adrenaline were measured [9]. Winkel et al. have also noted that while the clinical manifestation is that of sympathetic nervous system activation, parasympathetic activation may play a role in the overall autonomic dysregulation that occurs following envenomation.

In vivo and in vitro studies on *M. kingi*, a box jellyfish smaller than *C. fleckeri*, have demonstrated extra-cellular calcium-dependent vasoconstriction and positive inotropic actions, which, at high concentration, become cardiodepressive [10–12].

Physalia physalis venom contains numerous proteins capable of myriad effects. Physalitin, a potent hemolysin, comprises about 28% of the total protein composition of the venom [13]. The venom most likely damages target cells by insertion into plasma membranes with subsequent pore formation, potassium efflux, and colloid osmotic lysis [14]. Intracellular calcium influx, induced through toxin induced pore formation, may occur at in vitro exposure as low as 10 ng/ml [15]. The influx of calcium is associated with a release of intracellular lactate dehydrogenase (LDH). In a canine model, intravenous administration of *Physalia physalis* venom induced

arrhythmias, hypertension, hyperkalemia, hyponatremia, and hemolysis [16].

Pathophysiology

Chironex fleckeri is probably the most medically important jellyfish and is one of the most dangerous animals on the planet. Reports are variable, but over 70 deaths have been reported from *C. fleckeri* envenomation [17]. Swimmers may not observe the jellyfish prior to or even after a sting. Most stings are innocuous and prospective studies have demonstrated that the majority of victims will not experience life-threatening symptoms [18]. For severe envenomations, symptoms begin with severe, unrelenting pain. Autonomic dysfunction, manifest as hypertension, may progress to hypotension, apnea, and cardiovascular collapse. Dysrhythmias have been reported in piglet models [5]. Coma may occur after the sting, which, when in the marine environment, may lead to drowning. Death is more likely if the length of cutaneous exposure exceeds 3 m [19].

Carukia barnesi is capable of inducing the “Irukandji syndrome.” In fact, *C. barnesi* was once referred to as the Irukandji jellyfish, but other members of the carybdeid family (*M. maxima*, *C. shinju*) are also capable of inducing this syndrome. Like envenomation from *C. fleckeri*, the victim of a *C. barnesi* sting may never see the offending organism. The sting is generally felt within a few moments of contact. The pain is not usually as severe as that of the big box jellyfish. Systemic features may begin within minutes and are manifest as muscular pain (in particular low back) and cramping (abdominal wall and limb), vomiting, diaphoresis, agitation, and hypertension [2]. In one case series, the symptom/sign frequency was abdominal cramps (40%), hypertension (50%), back pain (39%), nausea/vomiting (39%), muscular cramping of the limbs (34%), chest tightness (26%), and distress (24%) [20]. Troponin elevation, EKG abnormalities, and echocardiographic findings ranging from mild systolic dysfunction to global myocardial dysfunction were reported in another large series of *C. barnesi* envenomations [21]. Fatal

intracranial hemorrhage has been reported in one case of an extreme sequela of envenomation [22].

Envenomation from *Malo kingi* is reported to occur hundreds of times annually with at least three reported deaths [23]. The jellyfish can be found throughout the Indo-Pacific region, but is more commonly reported around the Philippines and Japan. Contact with *Malo kingi* is generally less severe than that of *C. flexeri*, though immediate, severe pain, cardiovascular collapse, and pulmonary edema are described [17].

Physalia physalis envenomations are common occurrences along the Atlantic Coast of the USA but are not limited to these waters and cause major stings worldwide. Symptoms of envenomation are generally immediate and localized, but delayed symptoms and systemic features can occur. Common symptoms include localized pain (mild to severe) and paresthesias and often accompany a linear, papular, or bullous rash or urticaria. Systemic features include diaphoresis, tachycardia, nausea, vomiting, muscle pain, headache, chills, and transient paralysis of the affected limb [24]. Hemolysis and renal failure has been reported [25]. Immediate, severe pain/distress followed by apnea and cardiac arrest has been reported (Irukandji syndrome) [26].

Dermatologic effects from jellyfish envenomation may arise from distinct toxins. Immediate dermatitis, skin discoloration, and local pain are the most common syndromes following cnidarian envenomation [27]. The local immediate and persistent wheals following sea nettle stings are likely an effect of leukotrienes, histamine, and neutrophil chemotactic activity [28]. Prolonged lymphokine responses have been demonstrated following jellyfish antigens, suggesting a T cell function may be a driving factor in the pathogenesis of skin lesions [29]. Erythema nodosum has been reported following a sting from *Physalia physalis* [27].

Clinical Presentation and Life-Threatening Complications

The majority of people envenomated by jellyfish will experience mild to moderate pain with or without cutaneous manifestation. Many victims

Fig. 3 Incipient necrosis and blistering within 24 h of box jellyfish (*Chironex fleckeri*) envenomation (Courtesy of John Williamson, MD. From Ref. [133], p. 1469)

may never seek medical attention. Nonspecific symptoms include nausea/vomiting, diaphoresis, and malaise. The severity of the toxidrome is variable and marked most commonly by dermatologic, cardiopulmonary, and neurologic effects.

Dermatologic manifestation can include skin discoloration, bullae, and urticaria. The clinical findings following contact with *C. fleckeri* are reported to be “distinctive” and described as heavily marked in a crisscross pattern, with transversely barred wheals which may be 8–10 mm wide (‘frosted ladder’) [17] (Fig. 4a, b). Delayed hypersensitivity reactions, characterized by a maculopapular rash, can occur 1–2 weeks after exposure. Necrosis of the skin can occur (Figs. 3 and 4).

Cardiovascular effects may include tachycardia, hypotension, and cardiogenic shock.

Neurologic manifestations generally begin with localized pain at the site of envenomation. Headaches, syncope, vertigo, ataxia, and altered mental status (agitation, delirium) may occur. Local paresthesia and transient limb paralysis are reported after *P. physalis* stings [24]. One death from intracerebral hemorrhage has been described following envenomation from *C. barnesi* [22].

The “Irukandji syndrome” is a serious form of envenomation from the carybdeid family of jellyfish, most notably *C. barnesi*. The syndrome begins rapidly, usually within 30 min, and consists of severe muscle pain/cramps, vomiting, diaphoresis, agitation, hypertension, and potentially acute heart failure or intracranial hemorrhage.

Fig. 4 (a) Frosted crosshatched pattern pathognomonic for a box jellyfish envenomation. The victim of this sting died rapidly. (b) The enhanced frosted appearance is a

result of application of a spray of aluminum sulfate (Courtesy of John Williamson, MD. From Ref. [133], p. 1469)

Toxin-induced neuronal sodium channel modulation leading to excessive catecholamine release is the postulated mechanism for this toxidrome [2].

Diagnosis

The constellation of sudden severe pain in a swimmer/bather/diver with cutaneous findings is suggestive of a jellyfish envenomation. Visualization of the jellyfish is obviously a helpful diagnostic clue; however, the small size or transparency of some species may limit visual detection. Examination of shed tentacles left on a victim may be a helpful work up to definitively identify a jellyfish sting, otherwise skin scrapings may be helpful for identifying the species of jellyfish responsible for the toxidrome. Diagnostic tests should be used to identify/follow potentially serious effects from the envenomation (i.e., serial troponins, EKG, echocardiogram, head CT, creatinine).

Treatment

As all envenomations will occur while the victim is in the water, first priority should be to remove the person from the marine environment and onto land or a boat to avoid drowning. There is a lack of data, suggesting a benefit to pressure dressings, and some in vitro evidence, suggesting a harmful effect [30]; therefore, there is no support for their

routine use. Patients should be kept calm and still, if possible. Physically removing tentacles should take place, but cautiously. Seawater irrigation and using an instrument to remove the tentacles is often suggested, but there are no data to support this. Health care workers need to don protective gear until complete decontamination is achieved. Tetanus prophylaxis is generally recommended when applicable (i.e., previously unvaccinated or out of date), although these envenomations do not pose a tetanus risk.

There is an exhaustive list of chemicals anecdotally used to neutralize undischarged tentacles left on the bodies of victims. There is no uniform approach or consensus on the protocol for such treatment, and evidence is often lacking or conflicting regarding topical neutralization. A 5% solution of acetic acid has been suggested to reduce nematocyst discharge from *C. fleckeri* and *C. barnesi* [31] envenomations. There are conflicting reports regarding the benefit of acetic acid for *P. physalis*. Some reports describe pain relief after the topical application of acetic acid [32], while others report immediate nematocyst discharge in both *P. physalis* and *C. quinquecirrha* [33]. Hypotonic solutions (fresh water), ethanol, isopropyl alcohol, and meat tenderizer are not likely beneficial and may increase nematocyst discharge and therefore should be avoided. Aluminum sulfate surfactant (Stingose [Pfizer], West Ryde, Australia) has been shown to reduce pain following *P. physalis*

Fig. 5 Box Jellyfish Antivenom (Courtesy of John Williamson, MD. From Ref. [133], p. 1470)

[32]. Lidocaine 4% topical solution with or without acetic acid reduced nematocyst discharge from *C. quadrumanus* and *C. quinquecirrha*. Heat application has been used to treat Irukandji syndrome and has been shown to reduce pain following *Physalis spp.* and *C. alata* envenomations [34]. Parenteral opiate analgesia may be the only necessary intervention to control pain.

The only currently available antivenin for jellyfish envenomation is the Box Jellyfish Antivenom (Commonwealth Serum Laboratories, Melbourne, Australia) (Fig. 5). Indications for treatment include envenomation from *C. fleckeri* with manifestations of systemic envenoming or in those who have extensive local involvement causing extreme pain which does not respond to routine analgesic therapy. Each vial contains 20,000 units of antivenin, and current treatment recommendations are to administer 1–3 vials (same dosing for adults and children) intramuscularly or intravenously (preferred when feasible), though it has been suggested that higher doses may be required to achieve venom neutralization [4, 35, 36]. There also seems to be a time-dependent

component to efficacy, with studies indicating that antidote efficacy may be augmented with a prophylactic approach rather than waiting for symptoms to occur [35]. This approach is problematic because most envenomations are mild, and the antivenin is derived from animal plasma; thus, there is a risk for anaphylaxis and serum sickness. Anaphylactic reactions should be treated in the standard manner. Human randomized trials are lacking, and the use of the box jellyfish antivenin remains a controversial point.

Management of serious Chironex envenomations, using verapamil, a calcium channel blocker and smooth muscle relaxant, is controversial and potentially harmful. While some studies have found that death was delayed in mice treated with verapamil before and after administration of venom [37] and lethality could be reduced from 21 of 21 to 16 of 22 mice treated with venom obtained from tentacle extract [38], others have shown that verapamil failed to prevent any effects of the venom and worsened cardiovascular collapse and increased mortality [5]. Currently, it is not recommended to use verapamil in the seriously envenomated patient [17].

There is no specific antidote for “Irukandji syndrome.” Painful toxidromes can be managed with opiate analgesics, usually parenterally. The “Irukandji syndrome” may exhibit direct myocardial effects; therefore, fentanyl may be a reasonable opiate to start with (pure narcotic receptor action without myocardial effects or toxic metabolites) [20]. Intravenous magnesium has been used in cases of severe envenomation and has a theoretical advantage because it may decrease vascular resistance in hyperadrenergic states [2]. In one case series, blood pressure reduction and pain improvement were observed in patients treated with IV magnesium (10–20 mmol boluses) [39]. However, a randomized trial comparing IV magnesium to placebo in the management of Irukandji syndrome failed to prove a benefit [40]. Though not without controversy, the authors of this randomized trial suggested reconsideration of the use of magnesium in the management of Irukandji syndrome. The Box Jellyfish Antivenom is not

expected to provide benefit from carybdae jellyfish envenomations causing the “Irukandj syndrome,” and given the potential harm, it should be avoided if the culpable jellyfish is known. Phentolamine and nitroglycerine have been used in case reports to treat the severe hypertension associated with this syndrome. Cardiovascular collapse may require inotropic support and pulmonary edema should be treated in the standard fashion. Patients who are asymptomatic without medications for 6 h after exposure may be discharged home with follow-up and careful discharge instructions.

With *Physalia spp.*, there is also no specific antidote. Treatment is supportive with focus on decontamination and pain control. As mentioned previously, there is conflict regarding the use of acetic acid, but given the concern for increasing nematocyst discharge, acetic acid might be best avoided. Though not well studied, severe muscle spasm may respond to 10% calcium gluconate (5–10 mL slow intravenous push), diazepam, or methocarbamol [25, 41]. Delayed cutaneous reactions, which may coincide with fever, weakness, joint pain/stiffness, can be managed with a 10- to 14-day oral prednisone taper starting at 1–2 mg/kg/day [42]. Topical anesthetics, such as benzocaine spray and lidocaine ointment and oral antihistamines, may be soothing.

Since the majority of patients who suffer jellyfish envenomation will experience only mild symptoms, most patients will be appropriately discharged from urgent care or emergency department settings. Hospital, and more specifically intensive care admission, should be reserved for those patients who experience the life or limb threatening problems. This applies to situations where a severe toxidrome requires: Box Jellyfish Antivenom, high dose opiates where respiratory compromise is a concern, evidence of ongoing ischemia (i.e., troponin elevations), intracranial hemorrhage, need for mechanical ventilation, malignant hypertension and end-organ injury, pulmonary edema, anaphylactic reactions, acute heart failure or following resuscitation from cardiopulmonary arrest.

Other Hydrozoa

Approximately one-third of the 10,000 species within the phylum Cnidaria belong to the class Hydrozoa. The medically important hydrozoans are *Millepora spp.* (fire corals), *Physalis spp.* (discussed above in the jellyfish section), and *Lytocarpus spp.* (fire weed or fern weed).

Fire corals are found in the tropical and subtropical waters of the Caribbean Sea and Indian, Pacific, and Atlantic Oceans. They tend to habitat in shallow water. Nematocysts found on tentacles which protrude from pores of the coral can envenomate divers and swimmers who may mistake the fire coral for rocky structures. Fire coral often have brightly colored structures and are brittle and thus easily fracture.

Pharmacology

At least 13 different species of *Millepora* exist and there are reports of various toxic components. Purified components of *M. alcicornis* and *M. tenera* have been shown to elicit hemolytic and dermonecrotic effects [43, 44]. *Millepora* cytotoxin-1 (MCTx-1), from *M. dichotoma var. tenera*, was the first proteinaceous toxin to be characterized [45]. MGTx-1 belongs to the dermatopontin family and is cytotoxic and hemotoxic in animal studies. Phospholipase A2, isolated from *M. complanata*, is a vasoconstrictive and hemolytic compound in rats [46]. Milleporin-1, a distinct toxin from MCTx-1, has been isolated from *M. platyphylla* and is also hemolytic to human red blood cells in vitro [47].

Clinical Presentation and Life-Threatening Complications

Contact with *L. philippinus* induces painful and pruritic wheals. Symptoms following contact with fire coral generally begin within 30 min of contact. There is often burning and stinging at the site of contact. A pruritic, erythematous, vesicular, or raised rash develops soon afterward. Violaceous papules and plaques may be replaced by blisters

Fig. 8 Fire coral sting (Photo by Kenneth Kizer, MD. From Ref. [133], p. 1462)

Fig. 7 Fernlike hydroid print on the knee of a diver (Photo by Paul Auerbach, MD. From Ref. [133], p. 1461)

once resolved [48] (Figs. 6, 7 and 8). Though brittle, the backbone of the fire coral is sharp enough to cause lacerations or local trauma to the skin of those who contact it. Allergic and anaphylactic reactions would be suggested if systemic symptoms such as angioedema, bronchospasm, or diffuse erythema develop. Like all wounds from marine sources, secondary infections can occur. There is at least one case report of delayed nephrotic syndrome, pulmonary edema, and renal failure following exposure to fire coral [49]. Contact with *M. dichotoma* was reported to cause a full-thickness burn requiring admission to a burn unit [50].

Diagnosis

There is no routine or specific diagnostic testing to confirm fire coral or fire weed stings. The

differential diagnosis would include jellyfish stings or trauma from non-Cnidaria coral. There is no role for routine diagnostic testing to investigate systemic injury in the context of minor, local symptoms. However, if systemic features occur, renal function testing, chest radiography, and complete blood counts may be beneficial.

Treatment

Like treatment for jellyfish stings, treatment for fire coral or fire weed envenomations begins with removal from the water environment. Rescuers should put on gloves and carefully remove any remaining tentacles with an instrument such as forceps. The skin should be rinsed with salt water. Hot water immersion may be helpful in control of pain (Table 5) Acetaminophen or non-steroidal anti-inflammatory medications are generally sufficient enough to treat the pain associated with the sting, though in severe cases, opiates may be indicated. Application of ice packs is recommended for *L. philippinus* stings, but not dousing with urine, vinegar, or methylated spirits as these may increase nematocyst discharge [51]. Topical steroids and oral antihistamines reduced the severity of symptoms, but not skin manifestation in one case series of Red Sea Coral stings [48]. Allergic reactions and anaphylactic reactions should be treated in the standard fashion. In the reported case of nephrotic syndrome, a single-dose intravenous methylprednisolone

(120 mg), followed by oral prednisone (75 mg/d), was used [49]. Surgical debridement may be necessary if necrosis complicates the dermal effects. Tetanus prophylaxis should be employed in the appropriate circumstances.

ICU admission is indicated in the rare instance of severe anaphylaxis, sepsis complicating envenomation, or pulmonary edema.

Stingrays

Stingray point in the US state of Virginia gets its name from an event that occurred during Captain John Smith's exploration near Jamestown. He sustained a serious stingray injury while exploring Chesapeake Bay near the Rappahannock River, but he recovered and later ate the stingray for dinner (Stingray Point historic marker N 76).

Stingrays inhabit the oceans, bays, inlets, and rivers of temperate and tropical climates around the world [52]. Rivers around the world with species of stingrays include the Amazon, Niger, Mekong, and those in Australia [52–54]. Stingrays are flat fish that have wide muscular wings to swim, but they often burrow into sandy ocean bottoms and await their prey. They are cartilaginous similar to sharks; however, they will not attack or pursue a human diver or bather, and most injuries occur when they are accidentally stepped upon and the stingray reflexively flex their whip-like barbed tail producing a deep penetrating injury likened to a knife wound [53].

Some 2000 stingray injuries occur in the USA each year and many more worldwide [52]. One of the more tragic occurrences was the 2006 death of Steve Irwin, an Australian naturalist and TV personality known as the "Crocodile Hunter," when he sustained a cardiac wound from a stingray, emphasizing how quickly these encounters can turn deadly. His was not the first such fatal cardiac wound reported, a young woman died in New Zealand from a similar wound in 1939 [53]. A report in 1988 described a 12-year-old boy who sustained a penetrating chest wound from a stingray, received medical care, but died 6 days later at home from sudden cardiovascular collapse due to pericardial tamponade [54].

Table 1 Stingray families

True stingrays	True rays
<i>Dasyatidae</i> (Whiptail stingrays)	<i>Myliobatidae</i> (Eagle rays, Manta rays)
<i>Urolophidae</i> (Round stingrays, "stingarees")	<i>Gymnuridae</i> (Butterfly rays)
<i>Potamotrygonidae</i> (Freshwater stingrays)	<i>Rhinopteridae</i> (Cow nose rays)

Fig. 9 Four anatomic types of stingray venom organs (From Ref. [133], p. 1489)

Stingrays, and the less injurious rays, are represented by 150 species within three families (Table 1). Each family has a distinguishing tail with one to four serrated spines (Fig. 9). The most dangerous is the *Dasyatidae* family due to the location of the spine and the length (37 cm) of its tail increasing penetrating efficiency [52]. This sharp serrated spine, with rear-facing barbs, acts

like a knife that can impale itself in a human when the stingray is disturbed and then reflexively arches its tail in self-defense. The spines often break off in the victim, but this does not kill the stingray. The spine can penetrate neoprene boots worn by divers. The spine's sheath contains two longitudinal grooves that contain venom [52].

Pharmacology

The venom is poorly characterized but contains 5'-nucleotidase, phosphodiesterases, and other tissue spreading factors [52]. Some as yet uncharacterized component of the venom may have direct cardiotoxicity [52, 55].

Clinical Presentation and Life-Threatening Complications

Stingrays inflict a penetrating wound from which the barb spine cannot be easily removed. The venom itself has low toxicity but plays a role in the inflammatory response and pain felt at the wound site [52]. Wounds to the heart, liver, spine, femoral artery, and extremities have been reported [52–54, 56–60]. Potential complications include cardiac tamponade and internal bleeding, and the victim may present in decompensated shock requiring emergent resuscitation. Arrhythmias possible due to the venom in the absence of a cardiac wound have been reported [55]. The most common wound from stepping on a stingray is a wound to the foot or lower leg (Figs. 10 and 11). Pain from any of these wounds is often excruciating and lancinating in character, peaking in 15–90 min and lasting up to 2 days [52]. Pain can extend up the entire limb, and a variety of systemic effects including nausea, vomiting, seizures, muscle spasms to the degree where the individual cannot continue to swim, and hypotension may occur [52].

Treatment

Critical attention to the resuscitation from penetrating trauma is the key management for stingray

Fig. 10 The stingray lashes its tail upward into the leg and generates a deep puncture wound (From Ref. [133], p. 1490)

Fig. 11 Stingray spine tip broken off into the heel of a victim (Photo by Robert D. Hayes. From Ref. [133], p. 1490). See Color Fig. 11

injuries. Injuries to the head or torso may require airway management, fluid resuscitation, and potential need for chest thoracostomy or operative exploration in an operating room. Embedded chest and abdominal spines should not be pulled out blindly. Extremity injuries should be evaluated for vascular and nerve lacerations. Pain control in a stable patient will require immersion of an affected limb in hot water (45 °C/113 °F) [52]. Wounds may appear cyanotic centrally. Wounds should be both x-rayed and explored for retained foreign bodies which should be removed. Plain radiography may miss these thin spine structures, and direct wound exploration is mandatory [60]. Often local or regional anesthesia is needed to achieve adequate wound exploration and debridement [52]. Antibiotics are usually given for penetrating traumatic injuries from the marine environment and should be broad-spectrum to cover for organisms such as *Vibrio damsela* (now *Photobacterium damsela*) [52, 61]. Penetrating wounds to bowel should receive antibiotics to cover gram-negative and anaerobic bacteria.

Delayed complications from these wounds may include risk of cellulitis, septic arthritis, necrotizing fasciitis, and osteomyelitis. A pseudoaneurysm of the superficial femoral artery has been reported [62].

Scorpaenidae

The bony fishes of the family Scorpaenidae (Table 2) represent a diverse group of fish, from both freshwater and seawater habitats throughout the world (Fig. 12). They all have a bony plate

across their back from their eye to their gill, with spines that cover a venom gland. When pressure is applied to these spines, as when the fish is stepped on, they release their venom into the wound created by the sharp spine. A few species have importance in human envenomation, the most severe of which is the stonefish. Other species of spiny fish have also been implicated in less common instances of envenomation (Table 3).

The stonefish are the most toxic of this group of marine envenomations. These are bottom-dwelling fish, which have a natural camouflage to appear like a rock or coral. Additionally they can burrow into sand and lay motionless for long periods of time so to give the appearance to an inattentive diver that they are part of the coastal rocky bottom. At times algae overgrowth on their skin adds additional camouflage to their appearance. Most stone fish are found between the Tropics of Cancer and of Capricorn in Australian coastal waters, in the Indian and Pacific Oceans. They do not naturally live along North American shorelines. While envenomation can cause hypotension, muscle paralysis, acute pulmonary edema, and cardiac dysrhythmias, it is not usually lethal. Although some resources claim that stonefish envenomation could potentially be fatal, the only fatality in Australia is that of Dr. Joseph Wassell, which occurred in 1915 on remote Thursday Island in the Northern Territories [63]. Two other fatalities occurred in the Indian Ocean in the Seychelles and on Mozambique in the 1950s [63]. With modern supportive care, envenomations from this group of marine life are treatable and victims should survive with access to medical care [64].

Table 2 Scorpaenidae: bony fishes

<i>Synanceja</i> : Pacific and Indian Oceans, North or Tropic of Capricorn	<i>Scorpaena</i> : Pacific and Atlantic Oceans, Caribbean Sea	<i>Pterois</i> : Pacific Ocean including North American West Coast

Table 3 Other spiny venomous fish

<i>Thalassophryne nattereri</i> (Atlantic Toadfish)
<i>Thalassophryne maculosa</i> (Cano Toadfish)
<i>Hydrolagus coliei</i> (Pacific Ratfish)
<i>Chimaera monstrosa</i> (European Ratfish)
<i>Kathetostoma avarruncus</i> (Stargazer)
<i>Scatophagus argus</i> (Spotted Scat, Butterfish)
<i>Selenotocota multifasciata</i> (Silver Scat, Stripped Butterfish)

There are over 80 species of *Scorpaena*, but only a few have documented human envenomations, and none have been lethal. Like stonefish they are well camouflaged. They are in both the Pacific and Atlantic Oceans and are one of the most common venomous fish along the coast of Brazil [65]. The venom apparatus varies between species that may possess 10–15 dorsal spines, and 2 pelvic and 3 anal spines, each with venom glands.

The least toxic of the scorpaenidae group are the lionfish (*Pterosis spp*), which go by a variety of names including zebrafish, dragonfish, firefish, and turkeyfish [66–70]. They are endemic to southern hemisphere coral waters but have been introduced in the Atlantic and Caribbean and are

considered an invasive species along the US East Coast [71]. These are a favorite for aquarium hobbyists, as they are free-swimming fish with thin ornate spines and coloration. In aquarium owners, they have been responsible for envenomations of the hands and fingers due to efforts to handle the fish or clean the aquarium [66–68]. Even handling a lionfish which had been dead for 1 or 2 days can result in envenomation [66].

Pharmacology

The venom apparatus is contained in its grooved dorsal spines and pelvic and anal spines. The spines are covered with an integumentary sheath over a venom gland. Each venom gland may contain 5–10 mg of venom [64, 72]. These venoms present a complex mixture of substances when injected into the skin, but the end result is severe pain, tissue destruction, hemolytic activity, and systemic effects. Components of the venom include hyaluronidase as a tissue spreading factor, and the toxic components, stonustoxin, verrucotoxin, and trachynilysin. Stonustoxin, a

heat-labile protein purified from *Synanceia horrida*, is composed of alpha and beta subunits and has a molecular weight of 148,000 Da [72, 73]. In animal models, stonustoxin causes hemolysis and edema, through local vasodilation, but this is generally not seen in human envenomations [72]. Verrucotoxin, from *Synanceia verrucosa*, has two alpha and two beta subunits, with a molecular weight of 322,000 Da [74]. The beta subunit has a 96% homology with the beta subunit of stonustoxin [72–74]. Verrucotoxin inhibits calcium and activates potassium channels in frog atrial tissue, but human cardiac effects are rare [74]. Trachynilysin, from *Synanceia trachynis*, has a molecular weight of 158,000 Da. It causes release of acetylcholine at the neuromuscular junction and causes negative inotropy and cholinergic effects, possibly through calcium influx [72–74]. Other vasogenic amines norepinephrine, serotonin, dopamine, and tryptophan, and enzymes acetylcholinesterase, phosphodiesterase, arginine esterase, and 5'-nucleotidase are also present in these venoms [64].

Clinical Presentation and Life-Threatening Complications

When a stonefish is stepped on, and a diver is envenomated, the clinical effects include severe pain, which peaks within 60–90 min after envenomation, and may persist for up to 12 h [72–76]. It is often described as severe burning in nature [76]. Other symptoms may include headache, muscle aches, diaphoresis, vomiting, diarrhea, restlessness, delirium, seizures. A variety of both tachydysrhythmias and bradydysrhythmias have been reported, as have acute pulmonary edema, hypotension, syncope, and pericarditis [75, 76]. The wound is painful, may bleed due to venom components with anticoagulant activity, and will appear cyanotic or ischemic centrally with a perimeter of erythema [64]. Local vesicles and bullae may form, and local lymphangitis may occur. Wound healing is very slow, taking months to heal, with possible secondary complications such as deep abscess formation, granuloma formation, and neuropathy.

Envenomation from the *Scorpaena* species, and related spiny fish, causes similar signs and symptoms as stonefish but are less severe. Since some of these species, such as sculpin, are harvested for food, hand injuries in fisherman are more common in this group of fish. In rat models of envenomation, hypertension and tachycardia occur first, followed by vasodilation, hypotension, and bradycardia prior to death [77]. Some other species such as bullrout and soldierfish are often grouped with these fish as potential venomous species [77–80]. Stonefish antivenom has been shown in vitro and in animal models to have activity for some *Scorpaena* and soldierfish venom [77, 78]. Studies of bullrout venom, however, show its venom has no hyaluronidase or phospholipase activity and has no antigenicity with stonefish antivenom [80].

The envenomation from the lionfish is described as throbbing, but systemic signs or symptoms rarely occur [67]. Reviews of cases from North American poison centers show mild to moderate pain at the envenomation site, radiating up the affected extremity [66–68]. Local edema usually occurs, but vesicles and bullae formation are possible local effects of lionfish envenomation [66–68] (Fig. 13). Diaphoresis, chest or abdominal pain, and jaw tightness have occurred in a few cases [66, 67, 81].

Treatment

Treatment consists of basic first aid with immersion of the envenomated extremity in water as hot as can be tolerated without causing burns or scalding injury. This is to deactivate the heat-labile components of the venom. Hot water as high as 45 °C / 113 °F has been used but can give rise to first degree burns. Therefore, water temperatures should not exceed 43 °C (Table 5). Recommended immersion times range from 30 to 90 min. If recurrent pain occurs a repeat heat immersion can be tried. Appropriate level of analgesics should be given. Local or regional anesthetic blockade may be warranted, especially if embedded spines are present, and these need to be removed and the wound debrided and irrigated. Deeply penetrating spines

Fig. 13 Vesiculation of the hand 48 h after the sting of a lionfish (Photo by Howard McKinney. From Ref. [133], p. 1495)

especially in the soles of the foot or the palm of the hand may require surgical exploration and removal in the operating room. Radiographs to find retained foreign body are often needed. There is no support for the anecdotal use of folk remedies, meat tenderizer, antiseptics, or dyes to aid in local wound care. Cold immersion though should never be done. Antibiotics have been used as for any penetrating wound.

Stonefish antivenom is available in Australia through Commonwealth Serum Laboratories (CSL) of Australia (Fig. 14). It is indicated for severe envenomation. Each 2-ml vial contains 2000 units of equine-derived F(ab')₂ antivenom against *Synanceja trachynis*, but has been used for all stonefish envenomations. Dosing is based on the number of spinous puncture wounds as an approximation of venom load. If there are one or two puncture wounds, one vial of antivenom intravenously is recommended, if there are three or four puncture wounds then two vials can be used, and for cases with greater than four puncture wounds three vials have been used. If recurrent pain occurs, addition vials may be given [71]. Aquaria in other countries with stonefish may stock the antivenom even if unapproved locally. For example, major US aquaria that house these species may have the CSL antivenom for use with investigation new drug status. In the US consulting, the antivenom index may help locate which facilities carry the antivenom: (<http://www.aza.org/antivenom-index/>).

Fig. 14 Stonefish antivenom (Courtesy of John Williamson, MD. From Ref. [133], p. 1496)

Envenomation by *Scorpaena* should be treated as stonefish envenomation with hot water immersion, pain control, local wound exploration with removal of spines, and ongoing wound care. Wound infections with *Vibrio vulnificus*, *Aeromonas Hydrophilia*, *Edwardsiella tarda*, *Streptococcus iniae*, *Erysipelothrix rhusiopathiae*, and *Mycobacterium marinum* have been associated with marine infections including necrotizing fasciitis [64].

The symptoms from lionfish envenomation can be treated with warm water immersion and analgesia alone (Table 5). Cold therapy can worsen symptoms and is to be avoided [66]. Stonefish antivenom, although demonstrated in animal models to neutralize the cardiovascular effects of lionfish venom, is not used for these less symptomatic human envenomations [66, 78]. Wound exploration and radiographs to see if there is a retained spine may be needed [68], otherwise antibiotics should be reserved for cases which progress to cellulitis, lymphangitis, and tenosynovitis [66].

Catfish

Catfish are a diverse group of fish inhabiting both fresh and salt water environments. Notable for their barbels (“whiskers”), catfish lack scales, dwell at the bottom of rivers, lakes, streams and oceans, and may grow to 350 kg (*Pangasianodon gigas*). Eight families of catfish live underground, four families live in salt water. Some species of catfish have as many as four pairs of barbels (maxillary, nasal, and two chin), while others have none. The barbel is a special sensory organ, aiding in chemoreception and detection of food, and is not the organ responsible for envenomation. Catfishing is an important source of commerce, and important freshwater species include the channel catfish (*Ictalurus punctatus*), brown catfish (*Ictalurus nebulosus*), and black bullhead (*Ictalurus melas*).

All catfish, except the electric catfish, contain a hollow spine along their dorsal and pectoral fins. These three spines are covered with glandular tissue within an integumentary sheath and some contain barbed retrorse teeth [42]. The spines normally lie flat against the fin, but the animal may extend the spine in defense when it feels frightened. While the common route of envenomation is following puncture from one of these spines, there are reports of envenomation following handling of just the tail of some species (Arabian Gulf catfish and some Mississippi River species) [82, 83]. This is thought to occur through epidermal secretion of venom. Puncture wounds are more common than lacerations, though both occur. Hand injuries are commonly reported among those who handle catfish [82].

Pathophysiology

Catfish venom is species dependent, but in general, is a complex composition of hemolytic, dermonecrotic, and vasogenic proteins [84]. The potency is inversely proportional to the size of the fish [84]. When the integumentary sheath of the spine is broken, the heat-labile venom is injected into the wound. Crinotoxin, identified in *Arius thalassinus* and *Plotatus lineatus*, is secreted from the epidermis when the fish feels threatened

and can enter humans through broken skin. Smooth muscle contraction and prostaglandin release are two effects from envenomation from crinotoxin. Salt water catfish have reputedly more severe envenomations.

Clinical Presentation and Life-Threatening Complications

In general, there is little morbidity following catfish envenomations and death is a rare complication. The majority of injuries occur following handling of the fish. There can be lower extremity injuries from stepping on or brushing up against a catfish spine. In the case of *Arius thalassinus* and *Plotatus lineatus*, envenomation can occur from skin exposure to epidermally secreted toxin. The effects of catfish envenomation generally occur soon after the puncture or laceration from the spine. Pain may be intense and seemingly out of proportion to the exam and may extend centripetally. Left untreated, symptoms generally resolve within an hour. A robust inflammatory reaction leads to erythema, edema, local hemorrhage, and potentially skin necrosis [84]. Systemic findings, such as tachycardia, weakness, hypotension, nausea, vomiting, dizziness, paresthesias, loss of consciousness, and respiratory distress can occur, but are not common. Crinotoxicity is manifest by throbbing pain, tissue necrosis, and muscle fasciculations.

The major morbidity from catfish envenomation stems from secondary infections. Following injury from fresh water species, *Aeromonas hydrophila* inoculation is reported, while *Vibrio spp* infection may complicate envenomation from salt water species [84]. Other infectious considerations include *Mycobacterium terrae*, *Corynebacterium spp*, *Staphylococcus* and *Streptococcus spp*. [82] as well as *Edwardsiella tarda*, *Klebsiella*, *Erysipelothrix*, *Nocardia*, *Chromobacterium*, *Sporothrix* and *Actinomyces* [84].

Diagnosis

There is no specific diagnostic test for catfish envenomations. Given the potential for spine

dislodgement, routine use of radiographs seems appropriate to exclude foreign body. Secondary infections may resemble streptococcal cellulitis [82], though gram-negative cellulitis should be considered. Wound cultures may be a challenge to obtain given the small puncture size.

Treatment

There is no specific antidote for catfish envenomations. Treatment is primarily supportive and effectiveness may be time dependent. Hot water immersion is the most commonly utilized method to reduce pain. Catfish venom is heat-labile, and hot water immersion may inactivate venom proteins and limit local sequestration. Immersion in nonscalding water at 43 °C for 30–90 min or until analgesia is achieved is one approach (Table 5). Folk remedies such as pouring hot coffee over the wound, applying mineral salts, solvents, or other chemicals have no proven benefit. Another folk remedy, of doubtful value, is rubbing the wound with the gel-like material secreted from the skin of the traumatized fish. This is thought to act as a local vasoconstrictor and pain reliever. Local infiltration with an anesthetic such as lidocaine or bupivacaine may be a helpful adjunct.

Local wound exploration is paramount as retained spines may act as a source for infection and persistent pain. Radiographs are a reasonable adjunct to evaluate for a deeply penetrating spine or fracture. Like most puncture wounds or dirty lacerations, suturing should not be employed. Allowing the wound to heal by secondary intention is a more appropriate strategy. Tetanus prophylaxis is indicated in the previous unimmunized or if previous immunization is out of date. Careful observation and return for wound checks are important. Routine use of antibiotics empirically in high risks wounds (deeply penetrating hand or foot punctures) seems appropriate. Recommended oral regimens include ciprofloxacin, levofloxacin, trimethoprim-sulfamethoxazole, or IV carbapenems or cefepime. For cellulitis associated with bullae, vesicles or ulcers where *Vibrio vulnificus* is suspected, IV

ceftazidime, fluoroquinolones, plus doxycycline is recommended [64].

It is unlikely that ICU level care would be expected following a catfish envenomation. The most likely scenario would be sepsis in a susceptible host (immunocompromised or cirrhotic)

Amazonian Parasitic Catfish

Within the waters of the Amazon valley lives a strange creature with a reputation to swim into the urethra of unsuspected bathers, particularly during micturition. This catfish is known by several names including candiru, canero, vampire fish, toothpick fish, and urethra fish and is a member of the genus *Vandellia*. In addition to urethras, this transparent, parasitic fish has been reported to swim into vaginas, ears, noses, and anuses [85]. Adults may reach 40 cm (16 in.) in length, though most species are much smaller.

There is controversy regarding the legitimacy of human penetration by this fish, and the stories remained largely folklore over the last one hundred years. The fish has umbrella-like spines near its small head, which may extend and penetrate human tissue, thereby making removal difficult (much like the barb in some fish hooks). It naturally preys on fish, swimming against the stream into the gills of other fish where it attaches itself for a blood meal. Human “attacks” are likely accidental. While not venomous, the tissue damage and lacerations that occur from forceful removal have been reported to cause death from massive hemorrhage [86].

Treatment

While penile amputations and forceful extractions are documented treatments for human exposures [86], prevention with tight fitting bathing suits may be a more practical approach. High-dose vitamin C and fresh juice from the unripen fruit of the jagua tree (*Genipa americana*) may be used by locals in remote settings as citric acid is reported to soften or dissolve the spines of the fish and facilitate removal. In modern health care

settings, removal should involve a specialty trained surgeon (i.e., urologist). Unless severe hemorrhage or sepsis has occurred, ICU admission is unlikely.

Weeverfish

Nine species of weeverfish belong to the family *Trachinidae*, although a number of other fish are sometimes referred to as “weeverfish.” The weeverfish has venomous spines located on its first 5–6 dorsal fins and gills. The name *weever* is from the Old French (*wivre*, *guivre*, *vivre*) for “viper.” *Trachinus vipera* (the lesser weever) and *Trachinus draco* (the greater weever) are the most well-known. Other English names for the weever fish include adder pike, sea dragon, sea cat, black fin, scorpion fish, and stang. The weeverfish can reach up to 50 cm in length and are yellow-gray with a white belly. They are rugged animals, capable of surviving several hours out of water.

The weeverfish does not have a swim bladder. Therefore, it sinks to the bottom of the ocean when not actively swimming. Here, it buries itself under the sand and waits in ambush for unsuspecting prey to swim by. The spines of the weeverfish are associated with venom-containing glandular tissue. When the integrity of the glandular tissue is disrupted, after puncture, for example, venom is released through the spine and driven into the victim. The fish is easily provoked [87], but most injuries occur when the spines are accidentally stepped on by bathers or mishandled by fisherman. The lesser weeverfish is the most dangerous of all the weeverfish and is considered the most venomous of all fish in the temperate waters of the Eastern Atlantic, Mediterranean, Baltic, North, and Black Seas [87].

Pharmacology

The venom from the weeverfish is clear gray with an odor of ammonia. It contains several heat-labile, high molecular weight proteins, 5-hydroxytryptamine, and a protein responsible for releasing histamine in victim tissue, kinin-like

proteins, and several catecholamines [88, 89]. *Trachinus draco* venom (dracotoxin) contains large amounts of catecholamines and histamine and has cholinesterase activity [90] and hemolytic properties [91]. Trachinine, one of the two lethal fractions from *T. vipera*, has been described as the most lethal venom ever derived from fish venom [87], but is labile and loses its toxicity after an hour at room temperature. Serotonin (5-HT) is found in the venom of other animals (cone snail, box jellyfish, Portuguese man-of-war, etc.) as well as the weeverfish and is potent pain-inducing substance.

Pathophysiology

Release of serotonin into the victim’s tissue produces the characteristic pain associated with weeverfish envenomation. The histamine component is capable of producing wheal reactions, edema and erythema [87]. Central and autonomic system effects may be a sequela of the catecholamine component of venom.

Clinical Presentation and Life-Threatening Complications

Severe pain, immediately after the puncture, is the expected reaction. The pain, which is initially local, may radiate throughout the limb, becoming progressively more intense over about 30 min when symptoms peak. The pain has been described as burning, crushing, stabbing, and “neuralgic” and can be out of proportion to the exam and difficult to control [87]. The pain generally resolves within 12 h, though may persist for up to a year [42]. Edema, erythema, cyanosis, and necrosis may be associated cutaneous findings. Systemic effects such as paresthesias, diaphoresis, convulsions, syncope, bradycardia, chest pain, respiratory distress, and delirium have been reported [87]. Weeverfish envenomation has been associated with spontaneous abortions [92]. Death is a rarely reported complication and may be from sepsis rather than a toxin-mediated process [93].

As with all puncture wounds, secondary bacterial infections can complicate the toxidrome.

Gangrene, skin necrosis, and abscesses have been reported [87].

Diagnosis

There is no specific diagnostic test for weeverfish envenomations. Given the potential for spine dislodgement, routine use of radiographs seems appropriate to exclude foreign body. An accidental sting from a weeverfish should be in the differential diagnosis for any bather or fisherman who presents with severe pain and puncture wound if weeverfish are local species.

Treatment

There is no commercially available antidote for the treatment of weeverfish envenomations. The mainstay of treatment is geared toward analgesia. While the pain will generally resolve if untreated, the degree of pain can be severe. Immediate immersion in nonscalding hot water (43 °C) for approximately 30–90 min or until analgesia is obtained should be the initial treatment (Table 5). This may inactivate heat-labile proteins in the venom and limit local sequestration. Local anesthetic infiltration, for example, 1% lidocaine without epinephrine, can be considered. Application of cold packs may worsen the pain and therefore should be avoided [88]. Intravenous calcium gluconate has been reported to help alleviate refractory pain [94]. While nonsteroidal anti-inflammatory drugs may be sufficient for pain relief, opiates would be a reasonable option if the pain is severe and refractory to hot water immersion. Anaphylaxis should be treated in the standard fashion.

Dislodgement of the spine is unusual, but radiography seems a reasonable tool to exclude spine foreign body. Local wound exploration and copious irrigation is important, though wide incision and drainage is not advocated given that this spine rarely breaks off into the victim and there is morbidity associated with further destruction of tissue [95]. Treatment for limb edema is probably best handled by elevation of the affected limb rather than pressure bandaging [95].

Tetanus prophylaxis is indicated in the previous unimmunized or if previous immunization is out of date. Prophylactic antibiotics should be considered in deeply penetrating wounds particularly in the hands or feet, though some have advocated that routine antibiotic use is unnecessary [96]. If antibiotics are to be used, consider coverage for *Vibrio spp* given the salt water environment.

Requirements for admission to an ICU are unusual following envenomation from a weeverfish, though consider this for situations where large doses of opiates are needed to control pain, anaphylactic reactions, secondary sepsis, or septic shock.

Starfish and Sea Cucumbers

Only one of the roughly 1,500 species of starfish is medically important. *Acanthaster planci*, the crown-of-thorns, is widely distributed in the Indo-Pacific Ocean, as well as tropical and subtropical zones of the Red Sea and the east coast of Africa across from the Indian Ocean. A known predator of coral, the crown-of-thorns starfish can decimate coral reefs [97]. *A. planci* is one of the largest sea stars, reaching diameters up to 60 cm, and is the only sea star which contains venom in its spines [98]. Injury occurs when one of the many spines of the sea star punctures and penetrates human tissue; thus, it is important to wear protective gloves when handling them.

Sea cucumbers (*Synapta maculata*), members of the phylum Echinodermata, are found on the sea floor and have a worldwide distribution. They have a soft, elongated body and can reach upwards of 3 m. Several species are collected for aquarium habitats, while other species are cultivated for human consumption. While it would appear to be an easy target for prey, the sea cucumber contains holothurin, a neurotoxic substance to some marine organisms, and is also capable of ejecting a soap-like substance from its cloaca which can entangle would-be predators.

Pharmacology

Several in vitro experiments have demonstrated numerous effects of extracted *A. planci* venom.

Venom components have demonstrated hemolytic, antiproliferative, apoptotic, edema-forming, and capillary permeability-increasing activity [99, 100]. Mice injected with lethal factor extract from *A. planci* have developed hepatocellular necrosis [101]. Holothurin A and B, produced by the sea cucumber, is a saponin which acts as an anionic surfactant. In isolated canine cardiac sarcolemmal vesicles, holothurin seems to interact with membrane permeability and can influence calcium and sodium exchange [102].

Clinical Presentation and Life-Threatening Complications

While *A. planci* is predacious to coral reefs, human envenomation is accidental, generally the result of mishandling or stepping on the sea star. Pain (ranging from mild to severe), erythema or discoloration, bleeding, and edema are the typical manifestations [103]. The pain is often self-limited and may last upwards of 3 h. While local symptoms predominant, systemic effects such as paresthesias, nausea/vomiting, and muscular paralysis may occur and are likely the result of multiple puncture wounds [42]. Subcutaneous granulomas and induration as well as tenosynovitis have been reported [42, 98]. To date, there is just one case of fatal anaphylactic shock which manifest within minutes following a single-puncture wound from *A. planci* [103].

Handling sea cucumbers without protective gloves may cause contact dermatitis [42]. The major risk from exposure to sea cucumber toxin is ocular injury which may cause severe conjunctivitis and blindness [42]. Holothurin is reported to cause severe illness or death if ingested [42]. All species of sea cucumbers are poisonous if ingested.

Diagnosis

There is no specific diagnostic marker for exposure to either the sea cucumber or sea star. Because spine fragmentation into soft tissue has been reported, x-rays following puncture wounds from *A. planci* is reasonable.

Treatment

Earlier reports suggest rapid and dramatic report of sudden collapse following *A. planci* envenomation; however, these are of questionable validity. Nevertheless, the priority for treatment following exposure to the crown-of-thorn sea star should be prompt removal/retreat from the aquatic environment. Once out of water, immediate immersion of the affected body part in hot, but nonscalding, water should take place until analgesia is obtained. Local anesthetics can be used for pain control if hot water immersion has failed to provide significant relief. Opiate analgesics may be useful for refractory pain. Surgical excision may be necessary for retained spines [98]. Repeated steroid injections (2 mg triamcinolone acetonide diluted fivefold with 1% Xylocaine weekly) has been reportedly used for persistent subcutaneous induration from retained foreign bodies following *A. planci* envenomation. Anaphylaxis should be treated in the standard fashion.

The dermatitis from sea cucumber exposure can be treated with topical steroids or for severe reactions, systemic steroids [42]. Topical analgesics may facilitate exam and irrigation. Careful inspection for any signs of a foreign body and, if there is suspicion of ocular exposure, fluorescein examination to exclude a corneal abrasion is indicated. Prompt ophthalmology referral is appropriate if there is ocular involvement. Though not well studied, cycloplegic, mydriatic, and corticosteroid ophthalmic solutions have been suggestive as treatments for inflammatory keratitis in the absence of appreciable infection [42].

Octopuses

All species of octopus are venomous; however, the most poisonous mollusca species are the southern blue-ringed octopus (*Hapalochlaena maculosa*) and greater blue-ringed octopus (*Hapalochlaena lunulata*) [71]. These are found in warm semi-tropical waters of the Pacific Ocean around Australia, New Zealand, the Philippines, and as far north as Japan, and in the Indian Ocean with distribution in New Guinea, Malaysia, and Sri Lanka [71].

Fig. 15 Blue-ringed octopus (*H. lunulata*) with exposed blue rings, showing how varying states of expansion of chromatophores surrounding each ring can dramatically change the conspicuousness of the blue rings from relatively pale (a) to very conspicuous (b) (Photo by Roy Caldwell from: Ref. [104])

These are small creatures, usually less than 20 cm long even with its tentacles extended, and tend to prefer a habitat of shallow water tide pools. They are usually not found deeper than 10 m of seawater. This habitat makes them easily found by sea bathers, curious children, snorkelers and shoreline divers. While at rest and undisturbed, they have bands that are a yellow color; however, when agitated the body darkens and its rings, which contain chromatophores, turn bright blue [104]. A typical blue-ringed octopus may have 50–60 such brightly colored rings. Unfortunately in this state they become more fascinating to children and adults unwary of its toxic potential (Fig. 15).

Pharmacology

The venom of the blue-ringed octopus contains tetrodotoxin, the same toxin found in puffer fish,

the Oregon rough-skinned newt, and poison dart frogs. It is found throughout the blue-ringed octopus's body, but the venom delivery is via its salivary glands, and a strong ventral mouth and piercingly strong jaws [105]. They can inject their venom deep into muscle fascia. The purpose of the toxin is for the octopus to use to overcome its prey, usually crabs and shrimp, and with its' adjacent suckers can hold its food, while the tetrodotoxin is delivered via an injection through the skin. Other tissue spreading factors in the venom include hyaluronidase and vasogenic constituents such as histamine, tyramine, and serotonin. These substances may cause hypotension in experimental animals, but hypotension in human envenomation is not likely to occur.

Tetrodotoxin blocks peripheral voltage-gated sodium channels and produces rapid onset of weakness and paralysis in all motor nerves [42, 106]. Central nervous system effects are absent, and consciousness is maintained throughout in human victims.

Clinical Presentation and Life-Threatening Complications

The blue-ringed octopus does not envenomate while freely swimming. When a human gives the small blue-ringed octopus, a ride on an arm or hand the octopus can bite and envenomate [42]. This should never be done, unless the diver wears impermeable rubber gloves. At the bite site, usually two small puncture wounds are seen. Only minimal pain occurs at the time of the bite itself. Muscle aches and a stinging sensation ensue, followed by slight anesthesia at the bite site within 5–10 min. From the envenomation site, the sensations spread to the whole limb. Within a half hour, the bite site becomes red and swollen [42, 107–111]. Nausea, vomiting, hives, and itching all can occur. As the sodium channel blocking effect of the tetrodotoxin becomes systemic, perioral and tongue numbness occur. Subsequently, muscle weakness begins and can progress rapidly to complete paralysis. Bulbar palsies with diplopia,

dysarthria, and blurred vision occur. Inability to stand and walk occurs as larger muscles are affected, and deep tendon reflexes are lost [42]. As the muscles of respiration are affected, chest tightness and breathlessness occur. Progression to respiratory failure, complete flaccid paralysis, and death may occur unless medical intervention is delivered [42, 110]. Pupils may dilate and become unresponsive to light reflex, causing the physician to misdiagnose brain death.

Treatment

Treatment includes rapid recognition of the effects of the blue-ringed octopus bite and summoning of advance first aid. Early mouth-to-mouth respiration or bag-valve-mask ventilation to preserve ventilation may be necessary. In rare cases, endotracheal intubation with ventilator management is required [108, 109]. The duration of venom effects is quite variable but may last up to 10–12 h [71]. Complete recovery may require a few days. Unfortunately there is no antitoxin or antidote. Wound care for the bite site is also important [111]. Granuloma annulare has occurred with other octopus bites [112]. A light pressure immobilization bandage to occlude lymphatic flow might temporize the systemic spread of the toxin until definitive airway skilled personnel arrive [42].

Indications for ICU admission are generally related to cardiovascular and nervous system effects and would include progressive muscular weakness, respiratory insufficiency/arrest, and significant alteration of mental status or cardiac dysrhythmias.

Cone Snails

On display in the Pergamon Museum in Berlin is a 5000-year-old necklace of cone shells excavated from a tomb in the Mesopotamian city of Uruk, proving that the attraction for these beautiful shells dates back centuries [113] (Fig. 16). The *Conus* species contains many beautiful appearing

shells in which a living snail resides with an effective stinging apparatus for capturing its prey. Smaller *Conus* species feed on worms (vermivores) but are less toxic, while mollusk hunting (molluscivores) and fish-hunting (piscivores) are potentially toxic when they envenomate humans [113]. Over 700 individual *Conus* marine snails exist in the *Conus* species. While stings are rare, they are potentially fatal due to the unique and complex nature of the conotoxins in its venom [71, 114–122]. Most cases occur along the coastlines of the Pacific Ocean, and fatalities have mostly been due to *Conus geographus* [114, 115]. However, other *Conus* species are capable of a painful envenomation [71, 115] (Fig. 16).

Cone snails tend to burrow into the sand during the day and emerge at night to feed on fish or mollusks [71, 114]. The stinging apparatus of snail cones is shown in Fig. 15. The harpoon-like radular tooth is launched by the proboscis. Conotoxin venom is stored in the venom bulb which pumps it through the venom duct into the hollow barbed radular tooth. Since the snail itself is slow moving, this rapidly firing harpoon is effective at striking its prey, and the conotoxins secreted into its hollowed barbed tooth are effective at immobilizing it [71].

Pharmacology

The conotoxins are actually several hundred peptides, which share a disulfide bridge, but have great variation in their activity between species and even within the same species [113, 115–117]. The common mechanism of action is through ion channel blockade at different receptors including calcium, sodium, potassium, and acetylcholine channels (Table 4). Blockage of the nicotinic acetylcholine receptor subtype results in paralysis, usually only in the snail's prey, but human envenomation can produce diffuse muscle weakness. The alpha-conotoxin, which blocks neuromuscular acetylcholine receptors, is mechanistically similar in action to alpha-bungarotoxin. The mu-conotoxins, which block sodium channels, are mechanistically similar to tetrodotoxin

Fig. 16 Seven *Conus* species are shown. The large specimen at the extreme left is *Conus marmoreus*, the marble cone, the type species of the genus *Conus*, and at the extreme right is the geography cone, *Conus geographus*, the species causing the majority of human fatalities. The large specimen on top is the glory-of-the-sea cone, *Conus gloriamaris*, one of the most prized and valuable natural history objects of the eighteenth and nineteenth century. The four smaller shells on the bottom row are, from left to

right, *Conus cedonulli*, the matchless cone, a specimen of which once outsold a masterpiece by Vermeer; *Conus imperialis*, the imperial cone; *Conus purpurascens*, the purple cone; and *Conus magus*, the magician's cone. *C. cedonulli* and *C. imperialis* are vermivorous (worm-hunting) species; *C. gloriamaris* and *C. marmoreus* are snail-hunting species; and *C. purpurascens*, *C. magus*, and *C. geographus* are piscivores (fish-hunting cone snails) (Photo from: Ref. [113])

and saxitoxin. Both of these produce neuromuscular paralysis. One conotoxin peptide, an omega-conotoxin derivative, from the species *Conus magus*, the magician's cone, has been developed into the pharmaceutical agent ziconotide, used for intrathecal injection for central neurologic pain control [116, 118, 119]. It blocks the N-type calcium channel [119]. Other nonconotoxin peptides lack a disulfide bond and have other physiologic actions (Table 4). The conopeptide conantokin-G was originally called the "sleeping peptide," as it put young mice into a trance like state, when injected directly into the CNS, via its blocking action on the NMDA receptor [113].

Clinical Presentation and Life-Threatening Complications

Human envenomation occurs when a diver handles the shell unaware it is home to the snail. Slight pressure on the proboscis causes the radular tooth to penetrate the skin and may break off. The initial pain is similar to a bee sting, but may include localized edema or cyanosis. Depending on the

species involved, symptoms may be localized to pain, or spreading paresthesia with limb heaviness or numbness, and constitutional symptoms such as nausea and malaise [120, 121]. Serious *Conus geographus* envenomations can cause generalized motor weakness, bulbar palsy symptoms (diplopia, ptosis, dysarthria, dysphagia, aphonia), respiratory arrest, coma, and cerebral edema [120, 122]. Death may occur if medical intervention is unavailable or delayed onset paralysis occurs with respiratory insufficiency. The severe effects can last for several hours and take a few weeks before complete recovery occurs [71, 122].

Treatment

Careful attention to respiratory support is essential for patients with paralytic symptoms. Intubation and ventilator support is critical once signs of diaphragmatic weakness and impending paralysis occur. As with other heat-labile venoms immersion of the envenomated limb in hot water up to 45 °C/113 °F may provide pain relief, but analgesics may also be necessary (Table 5). One source has recommended

Table 4 Physiologic actions of some conotoxins

Omega-conotoxin	Voltage-gated calcium channel N-type blockade
Mu-conotoxins	Voltage-gated sodium ion channel blockade
Delta-conotoxin Iota-conotoxin	Voltage-gated sodium ion channel enhancer
Kappa-conotoxins	Voltage-gated potassium ion channel blockade
Alpha-conotoxin Psi-conotoxin	Ligand-gated nicotinic acetylcholine receptor antagonists
Sigma-conotoxin	Serotonin receptor 5-HT3 blockade
Rho-conotoxin	Alpha-1 adrenoreceptor blockade
Chi-conotoxin	Noradrenaline transporter blockade
conantokin	NMDA (<i>N</i> -methyl D-aspartate) receptor blockade
conopressin	Vasopressin release modulator/agonist
contulakin	Neurotensin receptor agonist

edrophonium, 2 mg IV as a test dose, similar to a tensilon test, with up to 10 mg IV in an adult, as a reversal agent for the neuromuscular blockade at the nicotinic acetylcholine receptor [71].

Indications for ICU admission are primarily related to neurologic or respiratory system effects and would include progressive weakness, respiratory insufficiency or arrest, coma, or significant altered mental status.

Sea Urchins

Roughly 950 species of sea urchins inhabit all the world’s oceans but are often found among coral reefs. Most sea urchins have spines measuring upwards of 3 cm, though some may reach 30 cm. Spines are a defense mechanism for the sea urchin and act as a physical barrier capable of inflicting an uncomfortable puncture to predators.

Not all sea urchins are considered venomous, given only those in the family Diadematidae and

Table 5 Hot water immersion as initial treatment for Marine envenomation

Stingray	Sea Urchin
Stonefish	Scorpionfish
Lionfish	Blue-ringed Octopus
Cone snail	Weeverfish
Catfish	Starfish
Fire Coral Physalia	Crown-of-thorns

Echinothuriidae have a venom apparatus. Venom is contained within the spines of the sea urchin or within pedicellariae, small clamp-like organs that can capture and hold onto prey (Fig. 17). Sea urchin spines can be broken after impaling humans, often as a result of mishandling or stepping on the creature. Regeneration of dislodged spines by the sea urchin is possible [123].

Pharmacology

Sea urchin venom contains several biologically active components including steroid glycosides, serotonin, hemolysin, protease and acetylcholine-like substances [124]. Cathepsin B/X, present in the *Echinometra lucunter* sea urchin, is thought to contribute to the painful, inflammatory process following envenomation [123]. *Toxopneustes pileolus* causes histamine release from rat mast cells, whereas contractin A induces contraction of tracheal smooth muscle in guinea pigs [125, 126]. The venom of the Pacific *Tripneustes* urchin contains a neurotoxin that targets facial and cranial nerves [42].

Clinical Presentation and Life-Threatening Complications

Local inflammatory reactions, edema, local sensory loss, or pain are common features shortly following envenomation by sea urchins [127, 128] (Fig. 18). The pain associated with envenomation is moderate to severe in intensity and has been described as burning or aching. Spines may

Fig. 17 Venom apparatus of the cone snail. (From Auerbach PS: Envenomation by aquatic invertebrates. In Auerbach PS [ed]: Wilderness Medicine, 4th ed. Philadelphia, Mosby, 2001, p 1481.)

Fig. 18 Globiferous pedicellaria of a sea urchin, used to hold and envenom prey (From Ref. [133], p. 1476)

be visible underneath the skin and those from *Diadema setosum* or *Strongylocentrotus purpuratus* may appear purplish [129]. Systemic features including nausea/vomiting, abdominal pain, paresthesias, muscular paralysis, syncope, delirium, hypotension, and respiratory distress may occur but appear to represent a minority of cases [130]. Osteoarthritis, tenosynovitis, fasciitis, and bursitis were reported in a cases series of envenomations from Reunion Island [131]. Urchin

granulomas may develop months after the injury [132]. Two cases involving multiple stings from a black sea urchin in Hawaii presented with bulbar polyneuritis and respiratory insufficiency 6–10 days after envenomation. One patient developed magnetic resonance imaging-documented meningoencephalitis, whereas the other had signs and symptoms mimicking Guillain-Barré syndrome, with hyporeflexia and elevated cerebrospinal protein levels [71]. Envenomation from the

pedicellariae may cause more severe symptoms and, in addition to severe pain and the systemic features described above, aphonia, hypotension, and death [71].

Diagnosis

There is no specific diagnostic study in the management of sea urchin envenomation. Differential diagnosis would include envenomation from other stinging fish or simple punctures wound from nonvenomous animals, corals. Given the possibility of spine fragmentation, x-rays should be considered for all envenomations. Consider ultrasound, CT or MRI if negative x-rays but strong suspicion for embedded spine.

Treatment

There is no specific therapy or antidote for sea urchin envenomation. Treatment should begin with immediate hot water immersion (nonscalding) for 30–90 min or until anesthesia is achieved (Table 5). Easily reachable spines or pedicellaria should be removed as persistent envenomation may continue. Analgesics, including opiates in severe cases, should be considered. Presumptive wound exploration without evidence of spine fragmentation should be avoided, as spine localization is unlikely. Some species of sea urchins contain a dye that stains tissue and may confuse the practitioner for retained foreign body, though this dye should fade in 36 h.

Surgical consultation, by either an orthopedic, plastic, or general surgeon, is indicated for deeply penetrating spines that are causing persistent pain, synovitis, or are the source for infection. Splinting the affected structure to avoid further fragmentation may be beneficial. There is no consensus on the routine use of prophylactic antibiotics or anti-inflammatories in the management of these injuries. Tetanus prophylaxis should be instituted when applicable (i.e., previously unvaccinated or out of date) (Fig. 19).

Fig. 19 Finger swelling from sea urchin puncture. A single spine entered the palm over the third metacarpal bone. Swelling was severe in the second and third digits (Photo by Paul Auerbach, MD. Courtesy of John Williamson, MD. From Ref. [133], p. 1478)

Intervention	Organism	Level of evidence
Acetic acid 5%	<i>C. fleckeri</i>	III
Stingose	<i>P. physalis</i>	III
Box Jellyfish Antivenom	<i>C. flexeri</i> <i>C. quadrigatus</i>	III
Magnesium sulfate	Carybdeid spp.	III
Hot water immersion	All stinging fish	III
Opiate analgesics	All painful envenomations	III
Stonefish antivenom	Synacea spp.	III

Seafood is a common cause of outbreaks of foodborne illnesses. Of these outbreaks, one report described scombroid poisoning as the most frequent [1]. In the United States and Europe combined, scombroid accounts for up to 40% of all reported seafood-borne food-poisoning outbreaks [1].

Scombroid poisoning has been recognized since the late 1700s and was first documented in 1830 [2]. It is also known as histamine fish poisoning because of the concentrations of histamine in fish causing the characteristic signs and symptoms described in this chapter. It is a foodborne illness that occurs in clusters worldwide, most commonly after the ingestion of improperly stored seafood, but has also been reported after the ingestion of cheese [3].

The term “scombroid” originates from the family of fish Scombridae and Scomberesocidae associated with the illness, although poisoning can occur after the ingestion of other types of fish, see Table 1 [5–7]. Scombroid fish are largely oceanic and distributed widely throughout all temperate and tropical seas, and some are found occasionally in Arctic and Antarctic waters (Fig. 1).

Scombroid poisoning has been reported in Europe, Asia, Australia, New Zealand, Africa, Canada, Europe, and the United States. Estimates of the incidence rate of scombroid poisoning in Denmark, New Zealand, France, and Finland range from two to five outbreaks per year per million people. However, in the United States,

Table 1 Fish implicated in scombroid fish poisoning

Family	Common name	Genus and species
Arripidae	Australian salmon	<i>Arripis trutta</i>
Clupeidae	Pilchard	<i>Sardinops sagax</i>
Clupeidae	Spotted sardines	<i>Amblygaster sirm</i>
Coryphaenidae	Dolphin fish (mahi-mahi)	<i>Coryphaena hippurus</i>
Scomberesocidae	Saury	<i>Cololabis saira</i>
Scombroidae	Frigate mackerel	<i>Auxis thazard</i>
	Little tuna	<i>Euthynnus affinis</i>
	Little tunny	<i>Euthynnus alletteratus</i>
	Skipjack tuna	<i>Euthynnus pelamis</i> or <i>Katsuwonus pelamis</i>
	Striped bonito	<i>Sarda orientalis</i>
	Bonito	<i>Sarda sarda</i>
	Pacific mackerel	<i>Scomber japonicus</i>
	Atlantic mackerel	<i>Scomber scombrus</i>
	King mackerel	<i>Scomberomorus cavalla</i>
	Spanish mackerel	<i>Scomberomorus maculatus</i>
	Cero	<i>Scomberomorus regalis</i>
	Albacore	<i>Thunnus alalunga</i>
	Yellowfin tuna	<i>Thunnus albacares</i>
	Bigeye tuna	<i>Thunnus obesus</i>
	Bluefin tuna	<i>Thunnus thynnus</i>
Xiphiidae	Swordfish	<i>Xiphias gladius</i>

Data from Refs. [3, 4]

Hawaii reports a rate of 31 outbreaks per year per million people [1, 6].

Signs and symptoms of scombroid poisoning are variable in presentation and duration and are similar to other diagnoses such as allergic reactions, potentially leading to underreporting. In developing countries, the most common source of contaminated fish comes from recreational

fishing as opposed to commercially caught fish. This is likely due to inadequate refrigeration, which is more common in the recreational setting than in commercial fishing [6, 8].

In the United States, The Food and Drug Administration (FDA) requires fish importers to develop a plan to prevent spoilage and contamination. Along with the United States Customs and Border Protection, the FDA inspects thousands of seafood shipments annually for safety [9].

Biochemical Basis of Scombroid Poisoning

Fish causing scombroid poisoning contain high concentrations of the amino acid histidine [10]. When these fish are improperly stored, histidine is converted to histamine by bacterial contaminants in the flesh of the fish. This usually occurs when refrigeration is delayed or the fish are kept at or above 70–90 °F [21.1–32.2 °C], although spoilage can occur at lower temperatures (>45 °F [>7.2 °C]) [11].

The conversion of histidine to histamine occurs via bacterial histidine decarboxylase. Bacterial species associated with this enzymatic activity include *Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Proteus (Morganella) morganii*, *Serratia marcescens*, *Enterobacter intermedium*, and *Plesiomonas shigelloides* [12]. The skin, gut, and gills of affected fish may be normally colonized with these bacteria, which can overgrow during inadequate refrigeration, or through secondary contamination from fish handlers [13]. Figure 2 shows the pathways of biosynthesis and metabolism of histamine after conversion from histidine [14].

In fish, most histamine is produced in the flesh around the intestines, which then diffuses into other tissues. Concentrations of 5 mg of histamine/100 g of fish are regarded as normal [15]. Mild symptoms of scombroid poisoning may occur at concentrations of 20 mg of histamine/100 g of fish. Severe poisoning is reported after the consumption of fish containing histamine concentrations of more than 100 mg/100 g [16].

Fig. 1 (a) Bonito; (b) Mahi-Mahi; (c) Swordfish (Adapted from <https://commons.wikimedia.org>)

Fig. 2 Biosynthesis and metabolism of histamine

Rapid chilling or refrigeration of fish immediately after catching is the most effective way to prevent histidine-to-histamine conversion. In the United States, government regulations require storing the fish at $\leq 40^{\circ}\text{F}$ ($\leq 4.4^{\circ}\text{C}$). However, more recently there have been bacteria identified with the ability to form histamine at temperatures as low as 32°F (0°C), which could theoretically cause scombroid poisoning [17].

Implicated fish may not have a specific odor or appearance, nor is visible spoilage necessarily evident. Once histamine is formed, it is heat stable and the toxicity of contaminated fish is not reduced or eliminated by cooking.

Pathophysiology

In humans, histamine is a naturally occurring molecule. It is released from mast cells and enterochromaffin-like cells such as basophils, and from neurons as a neurotransmitter. The effects of histamine occur via its actions on histamine receptors (H1–H4) located in the gastrointestinal, respiratory, cardiovascular, nervous and hematologic/immunologic systems, and the skin [8]. Histamine agonism at H1 and H2 receptors causes hives, itching, flushing, and variable effects on the cardiovascular system. On the heart, histamine has positive chronotropic and inotropic effects. Histamine has also been known to be directly arrhythmogenic, which can lead to severe tachyarrhythmias. Its effects on the vascular system include vasodilation and increases in vascular permeability [18–20]. Histamine acts on the respiratory system causing bronchospasm, edema, and inflammation via its direct effects on the H1 receptor. Additionally, histamine mediates mucus secretion in the respiratory system through the H2 receptor [21]. Agonism at H3 receptors causes headache, nausea, and vomiting. Less is known about the role of H4 receptors in scombroid poisoning [5, 22].

There is some controversy as to whether scombroid poisoning is related to ingestion of exogenous histamine alone or simultaneous impairment of histamine metabolism in the consumer.

Interindividual variations in histamine tolerance may also play a role.

Histamine is metabolized by two enzymes in humans. Diamine oxidase (DAO) is directly excreted into the circulation and the gastrointestinal tract making it a major enzyme in catabolizing extracellular histamine. In the cytosol, histamine *N*-methyltransferase (HNMT) catabolyzes intracellular histamine [22].

Individuals with genetically determined reductions in the activity of DAO and HNMT may have a lower histamine tolerance, and along with variation in ingested histamine concentrations, this may explain some of the variable presentations in disease severity [6, 22, 23, 24]. The most common polymorphisms of DAO are Thr16Met, Ser332Phe, and His645Asp. Individuals with the His645Asp polymorphism may have atopic symptoms even without high concentrations of histamine [25]. For HNMT, there have been two polymorphisms described, Ile199Val and Thr105Ile, with the latter being the most common. The Thr105Ile variant of HNMT is associated with reduced thermal stability of the enzyme and decreased HNMT activity [26]. In theory, individuals with this polymorphism should be more susceptible to histamine-mediated symptoms, although studies have a mixed consensus in demonstrating an association between the Thr105Ile polymorphism and the development of histamine-mediated symptoms such as atopy and allergic diseases [26, 27].

Another hypothesized mechanism of scombroid poisoning involves the inhibition of DAO and HNMT [28–30]. In decomposed fish, lysine is decarboxylated to cadaverine, a potent DAO inhibitor [31]. This mechanism of scombroid toxicity is debatable as biogenic amine concentrations, such as cadaverine, are typically insufficient in most decomposed fish to cause inhibition of DAO and HNMT [32]. It has been suggested that the synergy between multiple substances can be enough to inhibit these enzymes and potentiate histamine toxicity [8]. Medications such as isoniazid (a potent inhibitor of DAO) [33] or monoamine oxidase inhibitors and chloroquine (potent inhibitors of HNMT) [29] can inhibit enzymatic activity and thus play a role in potentiating scombroid poisoning.

Another possible mechanism contributing to scombroid toxicity is that an unidentified toxin (“scombrot toxin”) in fish causes mast cell degranulation and histamine release. However, in a study of patients with scombroid poisoning where measured histamine and its metabolites were found to be elevated and prostaglandin-M concentrations were unchanged, suggesting that mast cell degranulation was not the histamine source [34]. Despite evidence against mast cell degranulation, some have suggested a yet-unidentified toxin that causes degranulation of either basophils, mast cells, or both, without the release of prostaglandins [32].

Clinical Presentation

The signs and symptoms of scombroid toxicity usually occur within an hour after the ingestion of a contaminated food source, usually fish [3, 6, 8]. The clinical presentation commonly includes swelling, flushing, and hives, especially to the face, neck, and upper torso. Symptoms such as oral paresthesias, numbness or burning, peppery or metallic taste, abdominal cramping, nausea, vomiting, and diarrhea may be reported. As histamine receptors are distributed throughout the cardiovascular system, tachycardia, palpitations, hypotension, lightheadedness, and, less frequently, dysrhythmias may occur. In severe cases, cardiac dysrhythmias, bronchospasm, respiratory distress, and shock may also occur. These patients present similar to those with severe allergic or anaphylactic reactions.

Elderly patients and individuals with preexisting cardiac or pulmonary diseases may be more vulnerable to the cardiopulmonary effects of scombroid poisoning [35]. Other potential risk factors for more severe and prolonged presentation of scombroid poisoning include those who are taking medications which interfere with histamine metabolism as mentioned above. However, severe presentations of scombroid poisoning are described in otherwise healthy young persons who progressed to hemodynamic instability and cardiogenic shock after initially presenting with mild symptoms [36–39]. In these rare cases, the electrocardiogram demonstrated diffuse ST depressions and elevations along with elevations in cardiac enzyme,

suggesting myocardial ischemia and necrosis. Additionally, an echocardiogram done in one case revealed left ventricular hypokinesis and a severely decreased ejection fraction [37]. Patients who underwent coronary angiography did not show evidence of coronary artery disease, suggesting that the mechanism for myocardial necrosis is secondary to coronary vasospasm [39]. These cases typically evolve within a few hours of presentation.

Signs and symptoms of mild scombroid poisoning are self-limited and usually resolve within 24 h if untreated and within an hour if antihistamines are administered. In severe cases, patients may be symptomatic for up to 48 h [3, 6, 8]. Shock and death have also been reported in the past but not in recent years.

A spectrum of presentations have been described, and these may be classified as mild, moderate, or severe (Table 2) [40].

The clinical presentation of scombroid poisoning may be difficult to distinguish from an allergic reaction to seafood. Retrospective epidemiological data are often the only differentiating factor. In particular, those affected by scombroid poisoning more often present in clusters rather than as isolated individuals. Recognizing clusters may be difficult as not all of these patients will present to the same emergency department and some may not seek care at all. This clinical cue, therefore, may not be readily available unless multiple patients present simultaneously after sharing the same meal. Information on clusters provides useful information to public health departments who can intervene to reduce subsequent exposures.

Diagnosis

There is no definitive diagnostic test for scombroid poisoning. The diagnosis is made based on history and clinical presentation. Scombroid is suggested when the presentation is scombroid poisoning in the setting of ingestion of the typical fish species. As mentioned previously, the presentation of similar symptoms among other individuals who ingested the same food suggests an outbreak. The lack of previous allergies to the implicated fish ingested supports the diagnosis

Table 2 Recommended classification and treatment of scombroid poisoning

Severity	Clinical features	Treatment
Mild poisoning	Rash only or brief flushing; tachycardia	Observe for 2 h
		Consider parenteral antihistamines if condition fails to improve or worsens
Moderate poisoning	Rash and persistent flushing; tachycardia; headache and/or gastrointestinal symptoms	Overnight admission if symptoms slow to resolve
		Basic life support (ABCs, oxygen) IV access
		Parenteral antihistamines (H ₁ and H ₂ antagonists); repeat if necessary
Severe poisoning	Any of the above	Hospital admission
	And/or bronchospasm	Basic life support (ABCs, oxygen) and/or advanced life support
	And/or hypotension	IV fluids
	And/or airway compromise	Epinephrine
	And/or angioedema	Parenteral antihistamine (H ₁ and H ₂ antagonists); repeat as necessary
		Nebulized bronchodilators

Adapted from Ref. [40]

ABCs airway, breathing, and circulation, IV intravenous

of scombroid poisoning, but does not definitively rule out allergic reaction [3].

Once a suspected index case occurs, the source fish may also be tested by some regulatory agencies for tissue histamine concentrations, which is a good indicator of fish spoilage, even when fish are not obviously decomposed. However, identified specimens must be properly stored and frozen prior to analysis to prevent ongoing histamine

production [3]. Regulatory agencies have determined specific values at which a batch or lot of fish may be rejected based on histamine concentrations. In the United States, histamine concentrations in fish found to be at 50 mg/100 g or greater are considered to be potentially hazardous to humans and are rejected prior to coming to market [41]. Suspected culprit fish with histamine concentrations exceeding this threshold suggest the diagnosis of scombroid poisoning. Bacterial counts in suspected fish are not useful because processing the flesh subsequent to spoilage may destroy the responsible organisms. Unfortunately, information on tested source specimens is rarely clinically available, and outbreaks may only be identified retrospectively. Reporting to the local poison control center may facilitate early identification of an outbreak when the diagnosis is presumed or suspected.

Treatment

The treatment of scombroid poisoning is symptomatic and supportive. Although signs and symptoms are self-limited, the use of antihistamines such as H₁ (e.g., diphenhydramine, hydroxyzine or promethazine) and/or H₂ receptor antagonists (e.g., ranitidine or cimetidine) may reduce the severity and duration of the clinical effects [4, 12] (Grade III evidence). The efficacy of cimetidine has been found to be equivalent to or to exceed that achieved with H₁ antagonists alone [12, 42] (Grade III evidence). H₂ antagonists are easy to administer and lack the sedating side effects of H₁ antagonists, reducing delay in hospital discharge [11]. Additional supportive measures can include antiemetics for nausea and intravenous fluids when signs of dehydration are present.

In rare occasions, when individuals present with moderate to severe scombroid poisoning, more aggressive treatments are warranted (e.g., epinephrine and glucocorticoids). In patients with respiratory effects such as bronchospasm or those with preexisting underlying respiratory diseases, β_2 bronchodilators may be indicated.

Those with cardiac complaints or preexisting cardiac diseases should be placed on a cardiac monitor. Progression of clinical signs to more severe presentations require escalation of care, as in the case for anaphylactic shock (e.g., intubation or vasopressors). In cases of moderate to severe presentations of scombroid poisoning, hospital admission or observation may be required. When the diagnosis of scombroid is suspected but overlapping with the potential diagnosis of seafood allergy, it is reasonable to treat specifically for anaphylaxis and discharge stabilized patients with treatments for allergy, including corticosteroids, diphenhydramine, and an epinephrine autoinjector, with instructions to avoid seafood until after appropriate follow-up with an allergist.

When clusters of patients present, in addition to the above therapies, the department of health or local poison control center should be notified.

Indications for ICU Admission in Scombroid Poisoning

- Any patient with underlying cardiac or respiratory disease who is severely symptomatic
- Any patient with severe bronchospasm and respiratory distress which does not promptly resolve
- Any patient in vasodilatory or cardiogenic shock
- Any patient with cardiac dysrhythmias as a result of scombroid poisoning

Criteria for ICU Discharge in Scombroid Poisoning

Discharge is indicated when the severe effects have resolved or have been treated successfully.

- Resolution of
 - Respiratory distress such as tachypnea, wheezing, or stridor
 - Cardiovascular instability
 - Dependence on mechanical ventilation

Special Populations

Scombroid poisoning is usually mild and self-limited. However, certain patient populations are at risk for more severe or prolonged disease. These include the elderly individuals with a history of allergic and atopic diseases (e.g., eczema, asthma), concurrent use of certain drugs that inhibit histamine metabolism (e.g., isoniazid, nonselective monoamine oxidase inhibitors), or those with preexisting cardiac or respiratory diseases [4, 35]. Patients included in these populations should be strongly considered for observation and/or hospital admission.

Scombroid poisoning in pregnancy is unlikely to affect the growth or development of the fetus. There are currently no data to suggest that children are more susceptible to scombroid poisoning, but this may be due to presumption of an allergic reaction as a misdiagnosis in this group.

Common Misconceptions about Scombroid Poisoning

1. It is an allergic reaction.
2. It is due to ingestion of a toxin.
3. It occurs only from scombroid fish.

Key Points in Scombroid Poisoning

1. It is not an allergic reaction.
2. It is caused by ingestion of food, usually fish, containing high concentrations of histidine which is converted to histamine via bacterial conversion.
3. The mechanism of illness may be multifactorial.
4. It may occur with nonscombroid fish and, more rarely, with cheese.
5. Clusters of patients presenting from the ingestion of the same meal increase the likelihood that scombroid poisoning.
6. The onset of symptoms is usually within an hour after ingestion.
7. Most cases are mild and self-limiting, resolving within 2–3 h if antihistamines are given or within 24 h if untreated.

(continued)

8. Signs and symptoms vary; however, common symptoms include flushing, itching, hives, throbbing headache, dizziness, nausea, vomiting, and diarrhea.
9. Respiratory distress or cardiac complications are rare and usually occur in patients with preexisting pulmonary or cardiac disease.
10. Severe symptoms such as shock and acute coronary syndrome have been reported in otherwise young and healthy individuals and generally occur within a few hours of symptom onset.
11. Fatalities are reported.

Tetrodotoxin (TTX) with a toxicity more than 1000 times greater than sodium cyanide (median lethal dose approximately 10 µg/kg versus 10 mg/kg for sodium cyanide) is one of the most potent marine poisons known [1–3]. It also may be the best known marine toxin, because it is responsible for puffer fish poisoning (fugu or *Tetraodon* poisoning), which has caused many fatalities, particularly in Japan. Although puffer fish poisoning has been associated with a high fatality rate in Japan for centuries, the danger of puffer fish consumption has long been recognized in other countries, including China and Egypt [3, 4]. The first Chinese pharmacopoeia, the *Book of Herbs* (*Pen-T'so Chin*), usually attributed to the legendary Emperor Shun Nung (2838–2698 BC), listed puffer eggs as one of the 120 medium drugs that were believed to have tonic effects but could also be toxic, depending on the dose [3]. A detailed description of the appearance and general toxic properties of a puffer fish (known as “piglet of the river” in Chinese, likely representing *Tetraodon oscellatus*) was given in the most authoritative pharmacopoeia of traditional Chinese medicine, *The Great Herbal* (*Pen-T'so Kang Mu*), by Li Shih-Chen in 1596 AD [3]. A puffer fish identified as *Tetraodon lineatus* is shown on an Egyptian tomb from 2500 BC, and there is evidence that the Egyptians knew the poisonous nature of this fish [4].

Despite biblical admonitions prohibiting the consumption of scaleless fishes [5, 6], Europeans probably were unaware of puffer fish poisoning

until they began to visit the Orient in the seventeenth century. In his classic work *History of Japan*, published in 1727, Engelbert Kaempfer, a physician to the Dutch embassy in Japan, described the lethality of puffer fish and its use in suicide attempts [3]. Direct and well-documented European experiences of puffer fish poisoning first occurred during the second voyage of Pacific explorer Captain James Cook [1, 3]. In 1774, he and two naturalists, J.R. and G. Forster, on the *Resolution*, experienced various neurologic manifestations after eating a fish traded with a native in New Caledonia. According to his journal record and the Forsters' description of the fish, it is believed that they had been served puffer fish.

Puffer fish are also known as *blowfish*, *swellfish*, *globefish*, *porcupine fish*, *balloonfish*, and *toadfish* because they can take large quantities of water into the stomach when they are frightened or injured and assume an enlarged, globular shape. The skin of puffer fish is distinct because it is smooth or prickly and is covered partially by bristly or hairlike spines. Most puffer fish live in shallow warm waters. Puffer fish belong to the order *Tetraodontiformes*, which includes the families Tetraodontidae, the puffer fish; Diodontidae, the porcupine fish; Canthigasteridae, the sharp-nosed puffer fish; Molidae, the mola or ocean sunfish; Triodontidae, the three-toothed puffer fish; and others. Currently, there are at least 40 species of puffer fish that have been shown to be poisonous, most belonging to the family Tetraodontidae [1, 5]. The term *puffer fish poisoning* has been reserved largely for poisonings caused by ingestions of members of the family Tetraodontidae or, on some occasions, of other aforementioned families. In puffer fish, TTX is found mainly in the liver, ovaries, intestines, and skin [4, 5]. The musculature is usually safer to eat than other parts of the fish (especially when it is prepared by a licensed chef), but for some species (e.g., *Lagocephalus lunaris*), it can also be toxic [7]. The testes almost always are safe to eat, although they can be weakly toxic in certain puffer fish (e.g., *Spheroides niphobles*) [3]. Female puffer fish generally are more toxic than males, and the level of toxicity seems to be related to the reproductive cycle, with the toxicity

increasing from the beginning of the puffer fish season (usually, October through March) and reaching its peak during the spawning season (May and June, for most puffer fish) [3, 5].

In Japan, puffer fish have long been considered an epicurean delight, and it is believed that eating *sashimi*, thin slices of raw puffer fish meat, can give a peculiar tingling oral sensation, sensation of warmth, and euphoria induced by minute amounts of TTX contained in the flesh [5, 6]. For this reason, many Japanese regard eating fugu as a "must-have" experience despite the potentially severe toxicity of the fish. Some Japanese also believe that drinking a mixture of hot sake and fugu testes can contribute to virility and that adding a small amount of puffer fish liver can impart a particularly piquant flavor to certain dishes [1]. All of these eating behaviors may incur various risks of TTX poisoning.

Compared with the frequency of other food poisonings or the amount of fish consumed annually in Japan, the incidence of puffer fish poisoning is small; it is not considered a major public health hazard [3, 8]. Puffer fish poisoning is remarkable, however, for its dramatically severe course and for the multiple deaths that may occur in the same household [3]. Data obtained from the Ministry of Health and Welfare of Japan indicate that the overall case fatality rate of puffer fish poisoning, excluding the 6-year period of 1943–1948, was 59.4% in the period 1886–1963 [5] and was 36.7% in the period 1967–1976 [8]. Puffer fish poisoning accounted for more deaths than all other types of food poisoning combined in Japan [8]. Because of the popularity of eating fugu and the high case fatality rate, legislative controls, such as licensing of chefs in special restaurants requiring them to be knowledgeable regarding the species and seasonal variations in toxicity and education of the public, have been implemented in Japan to prevent puffer fish poisoning. As a result of these efforts and better therapeutic measures, the number of deaths caused by puffer fish poisoning per year declined from more than 100 persons in the late nineteenth and early twentieth centuries to approximately 20 during the period from 1974 to 1979 [3, 4]. Nevertheless, because the cost of the fugu

delicacy is usually high in Japan, people of low socioeconomic status continue to eat puffer fish that is prepared or sold privately by unlicensed peddlers, a behavior that increases the likelihood of poisoning [3, 5]. The statistics in 1957 showed that there were 119 incidents of puffer fish poisoning involving 176 persons [3]. Of these, only two incidents occurred after the eating of fugu in a licensed restaurant, neither of which had a fatal outcome. Of the remaining 174 persons, 90 died. Similar statistics also have been noted in other countries. In an analysis of Taiwan Poison Control Center data over the period 1988–1995, Yang and colleagues [9] found that among 18 incidents of puffer fish poisoning that involved 36 persons, only one victim purchased the fish from a restaurant, whereas the others collected the fish directly from the offshore waters by themselves or purchased them from fishmongers.

Puffer fish have a worldwide distribution and may extend from latitudes 63°N to 47°S. Although many cases have been reported from Japan, poisonings may be encountered wherever these fish are consumed [5]. Poisonings have been reported in many countries other than Japan, including the United States [10–12], Mexico [13], Brazil [14], Australia [15, 16], Europe [17], Papua New Guinea [18], China [5, 19], Taiwan [9, 20], Bangladesh [21], and several other Southeast Asian countries [5, 22–27]. Accidental poisoning due to consumption of mislabeled or improperly processed puffer fish also has occurred in Italy [6] and the United States [11]. Outside of Japan, accurate statistics of puffer fish poisonings generally are not available because reporting this poisoning is not a regulatory requirement [5]. Currently available, albeit incomplete, statistics from Taiwan revealed a case fatality rate of 16.7% for puffer fish poisoning in that country during the period from 1988 to 1995 [8], with an average of 1–2 deaths yearly [9, 20]. In a large outbreak of puffer fish poisoning that involved 141 Bangladesh victims in 2008, the case fatality rate was found to be 12% (17/141) [21].

Although TTX poisoning previously was thought to occur almost exclusively from puffer fish poisoning, more recent evidence has shown that the toxin can also be found in a wide variety

of seemingly unrelated aquatic organisms and amphibians, including the Australian blue-ringed octopus (*Hapalochlaena maculosa*) [28], other blue-ringed octopuses (*Hapalochlaena fasciata*, *Hapalochlaena lunulata*) [29, 30], other gastropod mollusks (Japanese ivory shell [*Babylonia japonica*], trumpet shell [*Charonia sauliae* and *Charonia lampas lampas*], and several species of *Nassariidae*) [5, 17, 31, 32], Indo-Pacific goby (*Gobius criniger*) [33], starfish (*Astropecten latespinosus* and *Astropecten scoparius*) [5, 34], crabs (xanthid crabs [*Atergatis floridus*], *Zoysymus aeneus*, and horseshoe crab [*Carcinoscorpius rotundicauda*]) [5, 35–38], ribbon worms (*Lineus fuscoviridis* and *Tubulanus punctatus*) [39], frogs (*Atelopus chiriquiensis* and *Atelopus varius*) [40], and salamanders and newts (Salamandridae family [true newts], e.g., true salamander [*Cynops ensicauda*], Oregon newt [*Taricha granulosa*], and California newt [*Taricha torosa*]) [5, 41–43]. Human cases of TTX poisoning have also been reported after the ingestion of goby fish [5, 9, 44, 45], gastropod mollusks [32], trumpet shell [17], blue-ringed octopus [29], and salamanders [46, 47] and after being bitten by a blue-ringed octopus [48–50]. Among these species, the finding of TTX in salamanders and blue-ringed octopuses merits further discussion.

In 1932, Twitty serendipitously found that the larvae of striped salamanders (*Ambystoma tigrinum*) became paralyzed after receiving grafted eye and limb buds from embryos of the California newt (*T. torosa*) [1]. No further extensive studies of the compound were carried out until the 1960s. In 1962, a potent nonprotein toxin, of which 1 mg was capable of killing 7000 mice, was crystallized and was named *tarichatoxin*. To the investigators' astonishment, it was found later that tarichatoxin and TTX were identical in their infrared and nuclear magnetic resonance spectra and in their characteristics in various chromatographic systems. Newts did not become intoxicated after exposure to TTX. It is apparent that the two biologically different species – puffer fish and newts – contain the same toxin.

The isolation of TTX from the posterior salivary gland of the blue-ringed octopus

Hapalochlaena maculosa was the first instance that TTX was found in extracts of the venom glands, in contrast to the identification of toxin in the skin, muscle, liver, ovaries, or eggs in other species [28]. The chemistry and pharmacology of extracts of *Hapalochlaena maculosa* were investigated after the occurrence of several human envenoming cases, including two fatalities, in Australia [47, 48]. The principal toxin present in the venom glands was found to be a neurotoxin, which initially was named *maculotoxin*. Although it is now believed that toxic components other than maculotoxin are also present in octopus venom (e.g., haplo toxin, histamine) [5, 50], there is little doubt that maculotoxin is TTX [28, 50]. Recently, TTX was found to be present in all body parts of *Hapalochlaena maculosa*, including high concentrations of TTX in the arms [51].

In addition to *Hapalochlaena maculosa*, a blue-ringed octopus-related TTX food poisoning incident occurred in Taiwan in 2010. After detailed toxin analysis and gene sequencing, the culprit octopus was identified as *Hapalochlaena fasciata* [29]. The authors did not report which body parts of *Hapalochlaena fasciata* contained TTX. However, TTX had previously been found in many body parts of *Hapalochlaena fasciata*, including the posterior salivary gland, arms, mantle, anterior salivary gland, digestive gland, testes contents, oviducal gland, and nephridia [30].

The origin of TTX remains a mystery. The erratic distribution of TTX in widely different species suggests that the toxin is acquired through the food chain as a consequence of consuming toxic marine algae. Evidence supporting this hypothesis has come from the discovery of a TTX-producing *Pseudomonas* species isolated from a red alga *Jania* [5, 52] and the skin of puffer fish [53], the observed difference in toxicity between cultured and wild puffer fish [8, 54], the documented transmission of TTX from one fish to the next in a feeding experiment [5], and the regional variation in toxicity of puffer fish [5]. Some investigators proposed, however, that the ability to synthesize TTX in various marine organisms and amphibians may be simply a coincidental genetic development because of its

Fig. 1 Chemical structure of tetrodotoxin

survival value [40]. The finding of unique exocrine glands for the secretion of TTX in puffer fish supports the possibility that puffer fish may actively produce the toxin [55].

Biochemistry and Pharmacology

In the 1950s, Yokoo and Tsuda independently crystallized TTX in a relatively pure form [1, 5]. TTX is an amino perhydroquinazoline compound with an empirical formula of $C_{11}H_{17}N_3O_8$ (Fig. 1) and a molecular weight of 319 g/mol [1, 3, 5]. It forms a colorless crystal and is a monoacidic base with a pK_a of 8.5 in aqueous solution [3]. It is soluble in water if a trace of acid is added but readily decomposes in strongly acidic or alkaline conditions [1, 3, 5, 56, 57]. The toxicity of TTX reportedly has been destroyed by the action of 2% sodium hydroxide treatment for 90 min [5]. Because TTX is a nonprotein toxin, it is relatively heat stable; frying, stewing, baking, or boiling for hours does not destroy the toxin [5]. Storage at -15°C for 12 h or exposure to sunlight for 20 days also does not change its activity [5]. Commercial canning processes do not significantly reduce the lethality of the toxin. In contrast to its heat stability, TTX is found to lose its activity markedly even after minor alterations of its chemical structure [2].

Although TTX is one of the most potent marine toxins, little is known about its mode of action. Current evidence indicates that TTX abolishes

propagated action potentials through its selective blockade of voltage-gated neuronal sodium channels [1–3, 5]. In some animal experiments, TTX has also been shown to reduce the production of acetylcholine [58, 59] and to depress cytochrome oxidase and acetylcholinesterase at high concentrations [5]. There is no universal agreement, however, on whether the toxin acts on cytochrome oxidase [3]; in most experiments, the toxin does not inhibit, or only slightly affects, acetylcholinesterase, even in high concentrations [59–62].

Pharmacokinetics of Tetrodotoxin Poisoning

Volume of distribution: widely distributed; more specific data not available

Protein binding: low; specific data not available

Mechanism of clearance: renal

Active metabolites: none

Methods to enhance clearance: none

Pathophysiology

The main pharmacologic effect of TTX appears to be blockade of the propagation of nerve and muscle action potentials by a nondepolarizing blockade of sodium channels [2, 3, 5, 57]. As a consequence, the neuromuscular effects are prominent, and rapidly progressive skeletal muscle paralysis, including muscles associated with respiratory function, is characteristic of TTX poisoning. Although TTX primarily inhibits the transmission of nerve impulses, it also has a direct action on skeletal muscle. This blockade of neuromuscular transmission generally is believed to occur on motor nerve axons and on muscle fiber membranes, rather than at the motor end plates [3, 60, 63]. After administration, the time required to inhibit muscle fiber function is usually longer than that for nerve block, except in the case of diaphragmatic muscle involvement [3, 63]. Slow muscle fibers are more susceptible to TTX than are fast fibers. Because TTX generally does not act on the motor end plate, the administration of anticholinesterase drugs, such as neostigmine or

edrophonium, is not likely to antagonize TTX-induced neuromuscular blockade effectively [3]. The axonal blockade caused by TTX is not limited to somatic motor nerves, and disturbance of sensory nerve function is frequently seen in the early phases of poisoning [3, 5]. TTX is approximately 160,000 times more potent than cocaine in blocking axonal conduction in sensory neurons [5].

Respiratory depression is the most prominent and serious toxic effect of TTX poisoning and is usually the cause of death among TTX-poisoned patients [3, 5, 63, 64]. Despite considerable controversy over how TTX produces respiratory paralysis, and the belief of some investigators that depression of the medullary respiratory center is responsible for respiratory arrest [5, 64, 65], more recent work has shown conclusively that TTX causes respiratory depression predominantly through direct paralysis of the diaphragmatic muscles [3, 57, 63]. The respiratory musculature is extraordinarily sensitive to TTX, and low doses of TTX (4% of the lethal dose) can depress respiration markedly in experimental animals [3]. Respiratory muscles may be more vulnerable to TTX than other skeletal muscles, or the phrenic nerve, because of their greater blood supply, resulting in a more rapid and proportionately greater distribution of toxin to the diaphragm [63]. Although central depressant effects are unlikely to be important in most instances of TTX poisoning, their role in the terminal stage of severe TTX poisoning, or after rapid intravenous administration of the toxin, cannot be dismissed [3, 57, 63]. Besides the inhibition of the respiratory musculature, TTX also causes depression of the cough reflex and relaxes bronchial smooth muscles [3].

Profound hypotension is a characteristic manifestation of TTX poisoning, which may or may not be associated with bradycardia [3, 62]. Hypotension has been noted as a cause of death in certain animal TTX poisonings [50]. Although a central vasomotor depressant effect previously was thought by many Japanese investigators to be the mechanism of TTX-induced hypotension [3, 5], the experimental evidence supporting this view was weak and unconvincing [3, 57]. Kao [2, 3],

in a series of head-body cross-perfusion experiments, showed that hypotension did not develop in the recipient's body when TTX, in a dose large enough to cause hypotension in the donor, was administered to the recipient's head via the donor's circulation. In other studies, the decrease in blood pressure was not accompanied by slowed heart rate or decreased cardiac output, which suggests that hypotension is attributable to direct peripheral vasodilation by TTX, rather than to cardiac depression [60, 64]. Large doses of TTX cause prolonged cardiac depression [2, 3, 62, 66] or conduction disturbances (e.g., bradycardia) [60, 66]; however, hypotension occurs before the cardiac depression at such doses [57, 66].

Most investigators now agree that TTX-induced hypotension is caused primarily by decreased peripheral vascular resistance rather than affecting the heart or the vasomotor center [2, 3, 57, 66], but the exact mechanism for this vasodilation is unclear. Some investigators believe that TTX causes hypotension by blocking sympathetic vasomotor nerves, causing relaxation of vascular smooth muscles [3, 57, 66]; others propose that TTX also has a direct effect on arterial smooth muscles [2, 67]. Kao [2] showed that the systemic hypotension seems to be due to a combination of a direct relaxant effect of TTX on vascular smooth muscle at low doses and blockade of vasomotor nerve conduction at high doses. Li [64] found that the TTX-related vasodilatory action had a histamine-like component because pretreatment with an antihistamine prevented the decrease in blood pressure caused by a sublethal dose of the toxin.

The effect of TTX on blood pressure seems to be dose dependent. In dogs, Nomiyama [5] found that small doses of puffer fish toxin produced an initial increase in blood pressure and heart rate followed by a decrease in blood pressure, whereas large doses produced immediate hypotension followed by a gradual increase in heart rate. Duce and colleagues [68] noted that nonlethal doses of TTX (0.6–2.4 $\mu\text{g/kg}$) resulted in an increase in heart rate and mean arterial blood pressure in unanesthetized dogs; higher concentrations of TTX caused moderate hypotension, apnea, and death. These investigators also

reported that TTX produced persistent hypotension and bradycardia in all anesthetized dogs and suggested that the difference between unanesthetized and anesthetized animals may be attributable to an indirect effect of TTX on the activation of the sympathetic nervous system or on a reduction in vagal tone. Hypertension has been noted in some human cases of TTX poisoning; almost all of them were of mild severity [9, 11, 20, 32]. It seems likely that, in nonlethal TTX poisoning, hypertension can be caused by an exaggerated reaction to sympathetic stimuli.

The primary systemic action of TTX is to block nerve conduction. Although TTX acts primarily on peripheral nerves, it can also cause central nervous system effects in sufficient doses. As previously mentioned, TTX may exert effects on medullary respiratory and vasomotor centers. TTX is also known to induce vomiting, a frequent manifestation of TTX poisoning [3, 5]. Because surgical ablation of the medullary chemotrigger receptor zone in dogs and cats abolishes this emetic action, vomiting seems to represent a central action of TTX [3, 69]. Nicotinic antagonism by TTX also has been suggested to be responsible for vomiting because tetraethylammonium (a nicotinic agonist), but not chlorpromazine or hexamethonium (a nicotinic antagonist), prevented the emetic action [5, 69].

In experimental animals, TTX causes a sustained decrease in rectal temperature [3, 65, 68], but little is known about the mechanism of this action. Anecdotal reports also suggested that TTX might have a central narcotic or sedative effect; and TTX subsequently has been used as a sedative in the treatment of opioid addiction [5]. Nevertheless, currently available data about the efficacy of TTX in the treatment of this addiction are inconclusive. Paralysis of the motor and sensory components of the spinal cord and indirect central actions of TTX, such as hypoxia-related convulsions, are among the other central nervous system manifestations that have been reported in TTX poisonings [5].

TTX blocks the neurally elicited responses of the autonomic nervous system [3, 5, 60] and may cause a decrease in gastric secretory volume, mydriasis, salivation, and hyperglycemia [5]. It

Fig. 2 Pathophysiology of tetrodotoxin poisoning

has been suggested that TTX may cause a pathologic state that is similar to the pathologic states of organophosphate or carbamate insecticide poisonings [70]. These toxic effects are not consistently observed, however, in animal or human TTX poisonings. Moreover, the autonomic nerves seem to be more resistant to the effects of the toxin than are the somatic nerves [5]. It also has been suggested that parasympathetic nerves are blocked by TTX before the sympathetic nerves [5] and that the postganglionic nerves are affected less severely than are the preganglionic cholinergic nerves [60]. Although TTX does affect autonomic nerves and probably vascular smooth muscle as well, it is unclear whether it has any direct effects on other smooth muscle or autonomic effector cells.

Few data regarding the pathology of human TTX poisoning are available. In reported cases [5, 8, 12, 20, 46], fatalities caused by TTX poisoning have been characterized by pulmonary edema and generalized congestion of the viscera. Localized changes in the gastric mucosa also have

been noted occasionally. There are no reported human neuropathologic alterations based on autopsy findings, although significant changes have been observed in experimental animals [5]. Figure 2 summarizes the pathophysiology of TTX poisoning.

Impure TTX was used widely as an analgesic in Japan in the early twentieth century [1]. Currently, there is no clinical utility for TTX in any practice because its anesthetic properties are generally attained only with near-lethal doses [5].

Clinical Presentation

There have been numerous reports of human TTX poisoning [5, 8–12, 14–27, 29, 30, 37, 44–49, 71, 72], and most humans were poisoned by ingesting puffer fish. Typically, symptoms begin within 10–45 min of ingestion, because TTX is absorbed rapidly from the gastrointestinal tract; [3] however, this may be delayed for 3 or more hours [5,

10, 15]. TTX poisoning usually manifests first with a tingling sensation involving the tongue and inner surface of the mouth and throat [5, 7, 9, 11, 12]. General malaise, pallor, dizziness, headache, ataxia, constricted pupils, nausea, vomiting, and sweating are also likely to be present early [5, 9, 11, 15]. Paresthesias subsequently may involve the fingers and toes and spread to other parts of the limbs [5]. In more severe poisonings, marked limb numbness, hypotension, cardiac dysrhythmias, dyspnea, and generalized weakness may develop, followed by respiratory paralysis, fixed and dilated pupils, and convulsions over the ensuing 4–24 h [5, 7, 9, 11]. Patients with severe TTX poisoning may become or look comatose, yet in most instances, their sensorium is intact [5, 15, 18]. Death in TTX poisoning generally occurs within the first 6–24 h [5, 7, 11, 15] and is usually the result of progressive respiratory paralysis [1, 5, 7, 9, 12, 21]. Less frequently, death may result from profound hypotension [1, 5] or other complications, such as hypertensive congestive heart failure among hypertensive patients [20] or aspiration pneumonia [30]. Death occurring as quickly as 17 min after TTX poisoning has been reported [3].

The onset and types of signs and symptoms of TTX poisoning can be diverse because they depend on the individual and the amount of toxin consumed [5, 7, 9]. Toxic features that have been reported are as follows:

1. *Neuromuscular*: [5, 9–12, 14–16, 18–21, 23, 25, 29, 32, 37, 44–46, 48, 71–73] circumoral numbness, paresthesia of phalanges and extremities, constrictive sensation of throat, dry mouth, floating sensation, generalized paresthesia, extreme weakness with walking difficulty, muscle twitching, tremor, incoordination, extensive limb paralysis, aphonia, dysarthria, dysphagia, backache
2. *Cardiovascular/pulmonary*: [5, 9–12, 14–16, 18–23, 25, 29, 32, 37, 44, 48, 71–73] hypotension, rapid and weak pulse, hypertension, cardiac dysrhythmias (sinus bradycardia, tachycardia, conduction block, asystole), chest tightness/pain, cyanosis, pallor, chilliness, facial flush, dyspnea, tachypnea, shallow respiration, aspiration pneumonia, acute pulmonary edema, acute respiratory failure, sudden death
3. *Central nervous system (direct or indirect effects)*: [5, 8–11, 14–16, 18–23, 25, 29, 32, 37, 44–46, 71–74] dizziness, vertigo, headache, drowsiness, lethargy, anxiety, transient/prolonged ataxia, blurred vision, hyporeflexia/areflexia, muscle fasciculation, convulsion, peculiar taste sensation, cranial nerve palsy, hypothermia, diabetes insipidus, reversible locked-in syndrome, coma
4. *Autonomic*: [5, 9, 10, 12, 14–16, 18, 19, 21, 32, 37, 44, 71–73] diaphoresis, initial miosis followed by mydriasis (or, rarely, prolonged constricted pupils), irregular pupils, reflex change of pupils, hypersalivation, urinary incontinence, bronchorrhea
5. *Peripheral sensorimotor nerve functions*: [5, 9, 16, 18, 71] diffuse reduction of conduction velocities and amplitudes of sensory and motor nerve action potentials in nerve conduction studies
6. *Gastrointestinal*: [5, 8–12, 14, 15, 19, 21–23, 29, 32, 37, 44, 46, 48, 71–73] nausea, vomiting, retching, hyperemesis, hematemesis, increased/decreased gastrointestinal motility, diarrhea, epigastric/abdominal pain
7. *Dermatologic (rare)*: [5, 73] exfoliative dermatitis, petechiae, blister, itching
8. *Miscellaneous*: [5, 9, 10, 16, 17, 19, 25, 44, 73] delayed coagulation of blood, hypokalemia, hypocalcemia, elevated hepatic transaminase levels, hyperglycemia, leukocytosis

Anecdotal reports also suggested that TTX might cause a “living dead” phenomenon; two patients recovered hours or days after they were pronounced dead in the late nineteenth century [5]. It is unclear, however, how the “death” diagnoses in these two patients were made and whether they were confirmed by any objective tests. TTX has been found in some voodoo potions used to transform a person into a creature of living death (zombie) of Haitian folklore

Table 1 Severity classification of tetrodotoxin poisoning

Degree of poisoning	Clinical manifestations
First degree	Oral paresthesia with or without gastrointestinal symptoms (e.g., vomiting)
Second degree	Advanced paresthesia and limb paralysis with intact reflexes
Third degree	Presence of gross muscular incoordination, dysphonia, dysphagia, respiratory depression, chest pain, cyanosis, and hypotension, with clear consciousness
Fourth degree	Coma, respiratory paralysis, and severe hypotension, followed by cardiac arrest in the absence of prompt treatment

Data from Fukuda and Tani (1941) [88]

[75, 76]; however, its role in zombification is questionable [77].

In 1941, Fukuda and Tani proposed a severity measure of TTX poisoning (Table 1) [5]. This scoring system is still used today.

Diagnosis

The diagnosis of TTX poisoning is based largely on clinical manifestations (i.e., the presence of typical neurologic manifestations, such as paresthesia and motor paralysis) and a history of exposure to puffer fish or other TTX-containing organisms. An accurate exposure history may not be available, however, and the clinical presentations of TTX poisoning may be atypical.

Some TTX-containing organisms also possess toxins other than TTX (e.g., saxitoxin) [5, 31, 36, 38, 49, 73, 78–80]. It is important to formulate a careful differential diagnosis that includes other neurotoxic exposures and nontoxic acute paralytic disorders. Among various marine poisonings, paralytic shellfish poisoning (saxitoxin) and ciguatera poisoning (ciguatoxin) are least likely to be distinguished from TTX poisoning based on clinical manifestations [6]. An accurate and detailed history is crucial because the species harboring these other neurotoxins are usually different from TTX-containing organisms [73]. A complete

physical examination, including a thorough neurologic examination, and electrophysiologic studies are helpful in making the final diagnosis of TTX poisoning; routine laboratory tests are not useful. TTX poisoning should be differentiated from anticholinesterase poisonings, such as those caused by organophosphate or carbamate pesticides or nerve agents. The differential diagnosis is unlikely to be difficult because TTX does not significantly affect cholinesterases [59–62], and cholinergic features are usually minor and transient in TTX poisoning.

The definitive diagnosis of TTX poisoning relies on the detection of TTX in poisoned patients or in the incriminating poisoning source. Specific methods for detecting TTX (e.g., gas chromatography–mass spectrometry, liquid chromatography coupled with tandem mass spectrometry) have been developed [8, 71, 78, 81]. The procedures are usually complicated, however, and the assay is not routinely available in most healthcare facilities. The clinical utility of these assays is therefore limited. More commonly, bioassay methods can be used to determine the toxicity of a suspected TTX source. These methods are reasonably specific when properly performed [3]. A commonly employed method involves the injection of dilute crude toxin intraperitoneally into mice. The toxicity is expressed semiquantitatively in mouse units (MU) per gram of specimen [3, 8, 9], and 1 MU (1 MU = 0.178 µg TTX) [29] is defined as the amount of toxin that kills a 20-g mouse in a standard period of time. It has been said that 200,000 MU of toxicity is the minimal lethal dose for humans [8, 20, 32], yet deaths after ingestion of lower doses of TTX have been reported [20, 32]. Although these bioassay methods can be performed easily, they are unlikely to be helpful in the early management of TTX-poisoned patients because they are generally unavailable in acute-care settings. Nevertheless, these methods can serve as a useful tool in confirming the diagnosis, especially when the exposure history is unclear or there is uncertainty about the incriminating source (e.g., in cases of mixed ingestion of various seafoods). Repeated exposure to TTX does not produce immunity.

Treatment

Indications for ICU Admission in Tetrodotoxin Poisoning

Respiratory paralysis or marked respiratory depression (i.e., difficulty in dealing with saliva or bronchial secretions, increasing dyspnea, rising respiratory rate, or worsening arterial blood gases)

Hypotension with impaired perfusion (e.g., oliguria, abnormal renal function, shock)

Symptomatic or significant cardiac dysrhythmia or conductive disturbance

Extensive neurologic dysfunction (e.g., coma, areflexia, fixed and dilated pupils)

Seizures

Other life-threatening complications (e.g., congestive heart failure, severe aspiration pneumonia)

There is no specific antidote for TTX poisoning [5, 57]. Treatment is mainly symptomatic and supportive. After exposure to TTX, rapid removal of unabsorbed toxin is theoretically important. If spontaneous vomiting does not occur, an emetic (often apomorphine) [5, 10] frequently is given, provided that there is no risk of aspiration [5, 6, 15]. This practice has not been shown to improve outcome, however, or alter the clinical course. Induction of emesis should be considered to be contraindicated because of an increased risk of aspiration. Gastric lavage may be used shortly after TTX poisoning (1–3 h; Level III evidence) [5, 10, 14, 15] in an attempt to remove toxin still in the stomach. This technique also has not been shown to improve outcome or affect the patient's clinical course. Although it is uncertain whether gastric lavage would be effective, theoretically it may remove some toxin even more than 3 h after ingestion because TTX can slow gastric emptying [5]. Therefore, the benefits of gastric lavage probably outweigh its risks among patients with TTX poisoning who present to the emergency department within one to three hours postexposure provided that airway protection is secured. Because

TTX is less stable in an alkaline environment, Sims and Ostman [10] suggested the use of 2% sodium bicarbonate solution (Level III evidence) in gastric lavage. The efficacy of this intervention is unproven, however. Activated charcoal is reportedly effective in early TTX poisoning (Level III evidence) [9, 10]. Some investigators even recommend endoscopy as a measure to remove the ingested toxin (Level III evidence) [44, 82].

After the occurrence of systemic manifestations, treatment should be aimed at the maintenance of adequate ventilation and circulation because respiratory arrest and profound hypotension are the two major causes of death [5, 15]. Supplemental oxygen is indicated in patients with hypoxia, hypoventilation, or respiratory distress (Level III evidence). Early endotracheal intubation and mechanical ventilation, which are potentially lifesaving interventions (Level III evidence) [9, 25], are indicated in patients with difficulty handling saliva or respiratory secretions, increasing dyspnea, hypoventilation or hyperventilation, or worsening arterial blood gases [5, 15]. Because patients usually are conscious, a full explanation of all procedures and sedation should be provided if intubation is necessary [15]. Tracheostomy is not necessary because recovery from TTX poisoning is usually rapid and complete within 24 h [5]. Antibiotics may be required in patients whose clinical courses are complicated by aspiration pneumonia [9, 23].

In patients with hypotension, fluid resuscitation should be given as indicated based on arterial blood pressure, urinary output, cardiac output, systemic vascular resistance, or central venous pressure [5, 15]. Vasopressor agents, inotropic agents, or both also may be required to alleviate hypotension if cardiac output, systemic vascular resistance, or both decrease or if central venous pressure increases without restoration of urine output. A target urine output of equal to or greater than 40 mL/h has been suggested (Level III evidence) [5]. Maintenance of a brisk production of urine is theoretically important in speeding recovery because TTX is eliminated mainly unchanged by the kidney within a few hours of ingestion [3, 57].

Among various inotropic agents, it has been shown in experimental animals that amphetamine, phenylephrine, and norepinephrine are the most effective in treating hypotensive effects of TTX, possibly due to their ability to stimulate directly or indirectly postsynaptic α -adrenergic receptors [51]. Epinephrine, probably because of its predominantly β -adrenergic effects, is less effective or in some instances detrimental [5, 51]. It is unclear whether these observations can be applied to human TTX poisonings. Some investigators have suggested the use of dopamine as the first-line inotropic agent (Level III evidence) [10]. Atropine can be given to patients with bradycardia, but its efficacy is controversial [10, 15, 16, 62]. Because bradycardia is rarely a serious problem in TTX poisoning, atropine is not routinely necessary. The electrocardiogram should be monitored continuously for cardiac dysrhythmias, however, and a temporary pacemaker may have to be inserted in cases of severe conduction disturbance (Level III evidence) [5, 15].

Hypertension in TTX poisoning is usually mild and transient [9] but may require treatment with antihypertensive medications in severe cases or in patients with preexisting hypertension [20]. Because of the possibility of the patient's progression from hypertension to hypotension, only short-acting antihypertensive agents, such as sodium nitroprusside, should be used (Level III evidence).

Several experimental therapeutic modalities have been suggested in the management of human TTX poisoning but their roles are controversial, and none has been scrutinized by large-scale prospective clinical studies [10, 19]. Anticholinesterase drugs (e.g., edrophonium and neostigmine), which can increase the concentration of acetylcholine at the neuromuscular junction, have been shown to be promising in some reports [15, 25] but not in others [3, 5, 9, 16]. Because TTX probably does not act on the motor end plate until its concentration reaches a high level [83], anticholinesterase drugs are not likely to be useful treatments [3]. In a recent systematic review of 23 case series and 14 case reports that provided some information

regarding the use of neostigmine in severe pufferfish-associated TTX poisoning, Liu and colleagues also concluded that the current literature was insufficient to provide an evidence base for or against the use of neostigmine in adults with TTX-associated respiratory failure (Level III evidence) [84].

Cysteine has been claimed to be potentially effective in the management of TTX poisoning [5, 10], and several possible mechanisms have been proposed [19]. Nevertheless, its benefit in human poisonings has not been documented. Other possible, yet unproven, therapeutic strategies for TTX poisoning are antihistamines, steroids, naloxone, veratrine-like agents, calcium, and hyperbaric oxygenation [5, 6, 19, 26, 73]. Antiserum and monoclonal antibodies against TTX have been developed and tested successfully in experimental animals [85–87], but their role in human TTX poisoning needs further research.

Hemodialysis instituted 21 h after TTX poisoning was reported to be effective in a uremic patient with profound neurologic dysfunction [45]. It is not clear, however, whether the relationship of this intervention to clinical outcome was more than a coincidence. TTX is only slightly water soluble under normal circumstances [3, 5, 57], and hemodialysis may not be an effective treatment. TTX has a low molecular weight and is minimally protein bound, however, which are properties often found in toxins amenable to hemodialysis. Despite these considerations, the short course of TTX poisoning and the effectiveness of mechanical ventilation and supportive measures undermine the potential benefits of hemodialysis.

The prognosis of TTX poisoning is usually favorable if adequate supportive measures can be instituted before cardiopulmonary arrest occurs. Because TTX can cause coma, areflexia, dilated pupils, or other signs of extensive brain damage early in the course of poisoning, resuscitation should not be abandoned prematurely even in the presence of the above-noted signs [16, 22]. If a patient survives beyond 24 h, the recovery is likely to be complete unless complicated by other life-threatening conditions [5, 6, 9, 15, 19].

Criteria for ICU Discharge in Tetrodotoxin Poisoning

Successful weaning from ventilatory support
 Normal blood pressure in the absence of inotropic agents
 Adequate control of life-threatening complications

Common Misconceptions About Tetrodotoxin Poisoning

1. Tetrodotoxin is found only in puffer fish.
2. The musculature of puffer fish is always safe to eat.
3. It is not difficult to differentiate between poisonous and edible puffer fish.
4. A puffer fish that was previously safe to eat is always nontoxic.
5. Puffer fish or other tetrodotoxin-containing organisms contain only tetrodotoxin.
6. Tetrodotoxin has a major effect on the acetylcholine-cholinesterase system.
7. Tetrodotoxin causes respiratory depression and hypotension mainly through its central depressant effects.
8. Tetrodotoxin poisoning always manifests hypotension.
9. The presence of extensive neurologic dysfunction in a patient with tetrodotoxin poisoning often indicates severe hypoxic brain damage, and aggressive resuscitation is unnecessary.

5. In puffer fish, tetrodotoxin is found mainly in the liver, ovaries, intestines, and skin.
6. The toxicity of puffer fish varies according to sex, species, season of the year, geographic locality, and organ of the animals.
7. The main pharmacologic mechanism of tetrodotoxin is to block the propagation of nerve action potentials by nondepolarizing blockade through its selective inhibition on the sodium channel.
8. Tetrodotoxin mainly affects the neuromuscular system, especially respiratory muscles.
9. Respiratory depression and hypotension are the two characteristic manifestations and the leading causes of death from tetrodotoxin poisoning.
10. Tetrodotoxin poisoning is not common; however, it has high mortality if proper treatment is not instituted promptly.
11. The treatment of tetrodotoxin poisoning is largely symptomatic and supportive. Treatment should be aimed primarily at the maintenance of adequate ventilation and circulation.
12. If a patient survives the first 24 h, a complete recovery should be anticipated unless complicated by other life-threatening conditions.

Key Points in Tetrodotoxin Poisoning

1. Tetrodotoxin is a heat-stable nonprotein toxin.
2. Tetrodotoxin can be found in a wide variety of totally unrelated aquatic organisms and amphibians.
3. Tetrodotoxin poisoning most commonly is caused by consumption of puffer fish, which has a worldwide distribution.
4. Puffer fish poisoning usually is the result of improper handling of the fish (e.g., private sale and preparation by fishmongers or vagabonds).

Mushrooms are the visible fruiting body of a fungus with the bulk of the organism usually below the ground and/or growing in substrate. Worldwide, mushrooms have important use as food, medicines, religious observance and dyes and are found almost everywhere on earth. Unfortunately, some mushrooms are toxic, and the number of mushroom species recognized as poisonous has grown in recent years. Additionally, because of world commerce and changing environments, some mushroom species are “migrating” and occasionally are found in places never before seen. Finally, when certain ethnic groups who are familiar with their traditional edible mushroom species move to a new area they occasionally suffer grave poisoning due to mistaken identification.

Mushroom ingestions are often associated with uncertainty because of the lethality of some species and the difficulty differentiating between types of mushrooms. Some basic understanding of the anatomy of a mushroom can be important for genus/species determination [1] (Fig. 1). When mushroom samples are collected, it is important that the bulb or volva be dug up using an appropriate tool because if a mushroom is simply picked, important morphological characteristics will be left behind. The annulus or ring may be fragile and easily dislodged and so the stem should be examined closely for remnants. Apparent puffballs should be cut open vertically and inspected carefully as young mushrooms that

are not fully developed have been mistaken for them. A spore print can be produced from a reasonably fresh mushroom cap; spore color and microscopic morphology can be extremely helpful for definitive identification. Spore prints are made by placing the mushroom cap spore-bearing surface down on a piece of white paper and covering the cap with a cup; if the mushroom cap is somewhat old and slightly dry, a single drop of water can be placed on the top of the cap before covering. The spore print generally takes at least 4 h to develop. Some mushrooms have distinctive morphological characteristics that can guide even the mycologically naive clinician in their diagnostic dilemma. These are described later in this chapter and in ► [Chaps. 108, “Cyclopeptide-Containing Mushrooms: The Deadly *Amanitas*,”](#) and ► [109, “*Gyromitra* Mushrooms.”](#) The assistance of a mycologist is often needed if there is a question of ingestion of a possibly poisonous mushroom. A poison control center, mushroom club, or botanical garden may be of assistance in identifying a local mycologist.

In many cases, management is not reliant on the exact species; even if the allegedly culpable mushroom is brought to the emergency department along with the patient, it may not be the actual mushroom species consumed. Multiple species often grow together, and some mushrooms contain multiple pharmacologically active compounds, further complicating the clinical picture. Laboratory tests to identify mushroom

Fig. 1 Anatomy of a mushroom

toxins are usually unavailable, and when they are, results may not be available for days to weeks. It is important to focus initially on the patient examination, clinical presentation in relation to the time of consumption, and emergent supportive treatment.

With the recent recognition of new mushroom poisoning syndromes, and the realization that some of the older clinical management “rules” are not always holding true, alternative categorization systems for the toxic mushrooms have been proposed. The categorization system proposed by White et al. [2] will be used in this chapter. However, due to the rarity and lack of critical illness for some of these mushroom poisoning syndromes, not every toxic mushroom will be included. Table 1 is a summary of the six groups of mushrooms known to cause human poisoning along with their toxin (when known) or species, its signature clinical effect, and a summary of commonly associated clinical effects.

Because of the overall paucity of information on mushroom toxicity, it is difficult to give evidence-based recommendations. In general, cases of mistaken identity of mushroom ingestions when cooked for food tend to be associated with greater toxicity than other scenarios. Conversely, unintentional exploratory ingestions of raw mushrooms by children are unlikely (but not impossible) to cause significant injury, with one series of almost 60,000 pediatric cases showing significant illness in less than 0.7% cases, with no deaths [3]. However, the toxicity of some mushrooms, is so great that a single mushroom ingestion can be lethal, emphasizing the need for caution.

Universal treatment recommendations for mushroom ingestions do not exist. Gastric lavage is not indicted following mushroom ingestion. It is not risk-free and has not been shown to alter outcome. Additionally, lavage tubes often have become blocked by mushroom fragments [4]. Activated charcoal may be used for gastrointestinal decontamination if there is a concern for amatoxins, but caution should be used because of the risk of aspiration, especially in the presence of altered mental status. Global treatment of any mushroom ingestion that causes gastrointestinal

distress with atropine is no longer recommended because it could exacerbate the toxicity of some types of mushroom ingestions.

Indications for ICU Admission in Mushroom Poisoning

- Evidence of significant end-organ toxicity (e.g., renal insufficiency or failure, elevated hepatic transaminases, rhabdomyolysis)
- Persistent altered mental status or status epilepticus
- Unstable or significantly abnormal vital signs
- Persistent hypovolemia with or without electrolyte abnormalities

Common Misconceptions About Mushroom Poisoning

- Gastric lavage has been shown to alter outcome after mushroom ingestion
- If a patient is ill early (<4 h) after mushroom ingestion, the patient will not become critically ill later

Key Points in Mushroom Poisoning

- Identification of mushrooms and their toxins is generally not readily available
- Occasionally, distinctive characteristics of the mushroom, knowledge of the species that grows locally, and clinical picture may be used together to include/exclude certain diagnoses
- Focus should be on the clinical course and supportive care of patients

Cytotoxic Mushroom Poisoning (Group 1)

This group contains mushrooms that cause toxicity by cellular injury and death, with the liver and kidneys being the primary target organs. Nearly all mushroom fatalities are due to the amatoxins, but there are some notable exceptions [5].

Table 1 Overview of selected mushroom poisoning groups (based on ref [2])

Group	Principal mushroom, toxin or syndrome	Primary clinical effect	Other clinical effects	Onset within 6 h?
Cytotoxic mushroom poisoning				
1A-Primary hepatotoxicity	Amatoxins	Hepatic failure	Nausea, vomiting, diarrhea, renal injury	No
1B-Primary nephrotoxicity	Aminohexadienoic acid	Renal failure	Nausea, vomiting, diarrhea, headache, fatigue, ±rash	Yes ^a
1C-Delayed Primary nephrotoxicity	Orellanines	Renal Failure	Headache, drowsiness, sweating, nausea/vomiting, malaise	No
Neurologic mushroom poisoning				
2A-Hallucinogenic	Psilocybin	Reality distortions	Nausea, vomiting, yawning, mydriasis. Not delirious; usually oriented	Yes
2B-Cholinergic mushroom toxicity	Muscarines	Cholinergic	Nausea, vomiting, diarrhea, fatigue, salivation, lacrimation, miosis, bradycardia	Yes
2C-Central nervous system toxicity	Ibotenic acid/muscimol	Altered mental status	Nausea, vomiting, flushing, wax/wane between mania and drowsiness, seizures, headache	Yes
2D-Morel neurologic syndrome	Morels	Vision changes, Headache	Nausea, vomiting, diarrhea, abdominal pain, asthenia, ataxia, sweating	Sometimes
Myotoxic mushroom poisoning				
3A-Rapid onset myotoxicity	<i>Russula subnigrans</i>	Rhabdomyolysis	Nausea, vomiting, diarrhea	Yes
3B-Delayed onset myotoxicity	<i>Tricholoma</i>	Rhabdomyolysis	Fatigue, myalgias	No
Metabolic pathway mushroom poisoning				
4A-GABA decreasing	Gyromitrins	Seizures	Nausea, vomiting, diarrhea, headache, hepatic injury	No
4B-Disulfuram like	Coprines	Flushing	Rash, headache, nausea, vomiting, diarrhea	Yes ^b
5-Gastrointestinal irritant mushroom poisoning				
6-Miscellaneous adverse reactions				
6A-Shiitake dermatitis	Lentinan (Shiitake)	Dermatitis	Linear rash/whiplike lesions, photosensitivity	Mostly No
6B-Erythromelalgic	Acromelic acid	Erythromelalgia	Swollen, red, painful hands/feet	No
6C-Paxillus	Paxillus syndrome	Hypotension	Nausea, vomiting, diarrhea, hemolysis, shock, AKI	Yes ^c

^aAlthough the GI disturbance begins within a few hours, the renal failure takes longer to develop

^bTiming dependent upon consumption of alcohol as well

^cSyndrome believed to require sensitization, so the initial exposure will only have minor symptoms

► **Chap. 108, “Cyclopeptide-Containing Mushrooms: The Deadly *Amanitas*”** covers group 1A. These are mushrooms containing amatoxins, which primarily cause hepatotoxicity. This chapter will discuss primarily nephrotoxic mushrooms

that do not cause significant hepatic injury. This group is interesting because in some cases the mushroom may have been ingested days earlier and thus that history element may be overlooked due to the delayed onset of symptoms. Of note,

other mushroom classes can result in renal injury through secondary mechanisms such as rhabdomyolysis (myotoxic mushrooms) and hypovolemia (metabolically toxic mushrooms and gastrointestinal irritant mushrooms).

Early Nephrotoxicity (Group 1B)

The primary clinical toxicity of this group of mushrooms is renal failure with onset somewhat earlier than the group causing delayed nephrotoxicity. The principal member of the early toxicity group is *Amanita smithiana*, but *A. boudieri*, *A. proxima*, *A. pseudoporphyria* and *A. echinocephala* have also been implicated [6–9]. *Amanita smithiana* is found in the Pacific Northwest of the USA and is commonly mistaken for the pine mushroom *Tricholoma magnivelare*; there are now members of this nephrotoxic group that have been identified in Europe [6, 8, 10]. *Amanita smithiana* usually is found growing under conifers. It is a light-colored mushroom that changes from a light brown to yellow-brown with age and handling. It has a large (5–12 cm) cap with white gills and spores and a long white, rough, bulbous (10–20 cm) stem with a ring; the *Amanita* stem characteristics will be lost if the mushroom is picked instead of being dug up [6, 10]. Older specimens of *A. smithiana* may have a strong unpleasant, putrid odor [7, 11].

Biochemistry

The compound responsible for the toxicity of *A. smithiana* has been proposed to be aminohexadienoic acid (2-amino-4,5-hexadienoic acid) [6, 12, 13]. The renal injury from aminohexadienoic acid observed in cell culture and animal models is similar to that seen after ingestion of *A. smithiana* and tends to occur after a latency period of up to 12 h [7, 13, 14]. However, there is uncertainty to this conclusion due to the relatively low concentration of aminohexadienoic acid compared to its LD₅₀ in animal models as well as its presence in non-nephrotoxic mushrooms. Based on thin-layer chromatography studies, it has been proposed for some (not *A. proxima*) of these mushrooms that the toxicity is due to an

“*A. smithiana* toxin” whose nature has yet to be determined [8]. Ingestion of one fruiting body of *A. smithiana* has been reported to cause renal injury in otherwise healthy individuals [7].

Clinical Presentation

Patients ingesting early nephrotoxic mushrooms usually have a short, but variable, asymptomatic period, ranging from 30 min to 12 h (average 5–6 h), although the reported very short onset times may have been due to a concomitant gastrointestinal mushroom ingestion [11]. Ingestions of *A. proxima* seem to have a longer onset of GI symptoms (average 13 h) compared to other members of this group [11]. This pattern of symptom onset in this group occurs more rapidly than that seen with orellanine-containing mushrooms (Group 1C) [11]. This pattern can be important in distinguishing these ingestions. Symptoms of nausea, vomiting, diarrhea, abdominal cramps, rash, myalgias, fatigue, headache, and weakness are characteristic and can last for days but may improve before the onset of renal failure. Patients intoxicated with *A. smithiana* tend to develop renal failure 2–5 days after ingestion. Occasionally, clinically insignificant hepatic transaminase elevations occur and LDH elevations have also been noted in patients who develop significant renal toxicity [6, 7, 11].

Diagnosis

The diagnosis of nephrotoxicity in this group of mushrooms is usually made based on the description of the ingested mushrooms and the clinical presentation, with many cases due to mistaken identity for the pine mushroom, *Tricholoma magnivelare*.

Treatment

No specific treatment for *A. smithiana* has been proposed. Approximately 90%+ recover renal function after about 4 weeks, but they may need hemodialysis in the interim [11]. The more rapid onset of injury that occurs with this group suggests that early dialysis is unlikely to be beneficial. A greater percentage of patients poisoned by *A. smithiana* recover renal function than do patients poisoned by *C. orellanus* [8]. Chronic

renal injury is not usually seen [11]. It is believed that patients with preexisting renal insufficiency are at greater risk for developing renal failure from *A. smithiana*. Elderly and diabetic patients intoxicated with *A. smithiana* tend to develop renal failure more rapidly than other patients [7].

Delayed Nephrotoxicity (Group 1C)

The primary nephrotoxicity of group 1C is similar to 1B but is more delayed. The mushrooms responsible are members of the genus *Cortinarius* which grows in semi-mountainous forests and is usually found from the end of summer through early autumn [15]. Nephrotoxic species include *Cortinarius orellanus*, *C. gentilis*, *C. speciosissimus*, and *C. splendens* [16, 17]. They are found mostly in Europe but occasionally in Australia and, less commonly, in North America [18, 19]. *Cortinarius orellanus* is difficult to identify because of a lack of distinctive morphologic characteristics. The caps are medium sized (2–5 cm) with orange or orange-brown to dark gray-yellow coloration with fine scales. The gills are rusty orange to dark orange-yellow, the stalk is thick with a yellow-to-orange color, and the spores are rust brown [1, 15].

Biochemistry

The nephrotoxicity of *C. orellanus* was first described in Poland in 1956; this relatively recent recognition was because of the long delay between ingestion and the development of renal failure [20]. The toxic compound in *Cortinarius* mushrooms is orellanine, a cationic bipyridine similar to paraquat, present in amounts up to 1.4% by weight (Fig. 2)

[21, 22]. It is a resilient toxin, resistant to heat, freezing, and drying, although it is light sensitive [21, 23, 24]. Orellanine is concentrated in renal tissue, possibly due to active cellular uptake. The exact mechanism of toxicity of orellanine is unknown, but evidence suggests that it causes a disruption of cellular cytoskeleton actin filaments and inhibits protein synthesis [23, 25, 26]. Orellanine requires activation by mitochondria (or possibly light) before becoming cytotoxic [16, 26]. *Cortinarius* spp. also contain cortinarin A and B which are cyclopeptides that may contribute to nephrotoxicity [16, 17, 22]. Ingestion of one fruiting body of *C. orellanus* has been reported to cause renal injury in otherwise healthy individuals; however, a dose of approximately 100 g usually is required [20, 27].

Clinical Presentation

Acute renal failure has been reported to develop in approximately 60% of orellanine-poisoned patients, but this percentage has been found to depend on the amount eaten, the age of the mushrooms, and the environmental conditions [28, 29]. The onset of *C. orellanus* toxicity is delayed, with no early symptoms. Patients who ingest *C. orellanus* are typically asymptomatic for 2–14 days (median 3 days and maximum 17 days) [7, 18, 24, 27]. Symptoms consist of nausea, vomiting, abdominal pain, chills, lumbar pain, malaise, dizziness, paresthesias, myalgias, headache, polydipsia, and polyuria followed by oliguria or anuria [20, 24, 28]. Renal insufficiency (median onset 8.5 days) has been reported to occur in approximately 70% of all ingestions [24]. Severely poisoned patients tend to present earlier. The onset of symptoms coincides with the clinical manifestations of renal failure rather than occurring as a separate prodrome as with *A. smithiana* (group 1B) [30, 31]. Recovery of renal function after poisoning (if it occurs) may take several weeks. Of patients poisoned with *C. orellanus*, about half develop chronic renal insufficiency or failure and hypertension [15, 16, 18, 25, 28, 29]. Elderly patients tend to have less renal improvement after poisoning by *C. orellanus* and require dialysis longer than younger patients [18].

Fig. 2 Chemical structure of orellanine

Diagnosis

The diagnosis of nephrotoxicity from group 1C is usually made retrospectively based on descriptions of the ingested mushrooms and the clinical presentation, realizing that there may be a delay of days between ingestion and symptom onset. After ingestion of *C. orellanus*, leukocyturia, proteinuria, and hematuria are typically observed early in the clinical course [16, 32]. Orellanine may be found in urine for 24 h after ingestion but cannot be found in urine, plasma, or dialysis fluid after onset of symptoms [27, 33, 34]. Orellanine may be assayed by high-performance liquid chromatography or thin-layer chromatography, but these tests are not routinely available [34, 35]. A qualitative test for orellanine in a mushroom sample can be done using ferric chloride. This test is accomplished by crushing fresh or dried mushrooms in five parts of water, let stand for 10 min at room temperature and filter. The filtrate is mixed with an equal amount of 3% ferric chloride hexahydrate dissolved in 0.5 M hydrochloric acid. The presence of orellanine is suspected if a dark gray-blue color appears [30].

Renal biopsy findings of patients with *C. orellanus* poisoning have shown acute tubular necrosis, interstitial edema, initial interstitial fibrosis, and inflammatory edema; tubulointerstitial nephritis is the most common biopsy finding [18, 24–26, 32, 33, 36]. Rat studies show interstitial and tubular epithelial pathology beginning within 12 h of poisoning; however, rats exhibit great variability in sensitivity to orellanine-induced renal injury [27]. Orellanine has possibly been detected in small quantities in renal tissue biopsies weeks after ingestion, but this has not been well studied and there are concerns of analytical limitations [24, 34].

Treatment

Treatment options for orellanine poisoning are limited because the patient is unlikely to present during the asymptomatic period early after the ingestion. Patients in renal failure should be admitted for monitoring and possible hemodialysis. Although some advocate early, aggressive dialysis, the benefit of this intervention is questionable because the toxin seems to be dialyzable

only within the first 24 h. The injury occurs subclinically as early as 12 h, and clinical presentation is typically delayed [27, 31, 32]. Orellanine crosses the dialysis membrane and has been shown to adsorb onto hemoperfusion resin [31, 33]. There is extremely limited clinical experience using hemoperfusion, but anecdotal data suggest improved outcome; plasmapheresis has also been used [33, 37] (grade III evidence). Other treatments have been tried on an individual basis, including corticosteroids, acetylsalicylic acid, diltiazem, and dopamine, but none have demonstrated any effect on clinical outcome [29]. Furosemide worsened outcome in animals [33, 38]. Some patients have received renal transplantation [30, 31].

Nephrotoxic Mushrooms

- Include *Cortinarius* spp. and *Amanita smithiana*
- *Cortinarius* spp. ingestion associated with delay of days before symptom onset
- May need hemodialysis for renal failure

Neurotoxic Mushroom Poisoning (Group 2)

This group contains mushrooms that primarily cause neurotoxicity, including both peripheral and central effects. This chapter will discuss the mushroom subgroups hallucinogenic, cholinergic, central nervous system toxic and the more neurologic syndrome.

Hallucinogenic Neurotoxic Mushroom Poisoning (Group 2A)

The mushrooms in this category are sometimes referred to as “magic mushrooms” due to their hallucinogenic properties. The toxicity from this group of mushrooms is from the active compound(s) psilocybin and psilocin, which are present in many different genera and species of mushroom, with the genus *Psilocybe* being the most frequently encountered. *Psilocybe semilanceata*

(“liberty cap”), *P. stuntzii*, *P. cubensis*, *P. cyanescens*, and *P. baeocystis* are some of the more commonly encountered species [39]. Other genera containing psilocybin include *Panaeolus*, *Stropharia*, *Conocybe*, *Gymnopilus*, *Inocybe*, and *Pluteus* [39, 40]. Psilocybin-containing mushrooms are found worldwide. For example, in the USA, they are more common near the Gulf of Mexico and in the Pacific Northwest.

The morphology of psilocybin-containing mushrooms is varied; generally they have smooth, light-colored caps, elongated stalks, dark gills, and dark spores which are occasionally purple/black in color. A characteristic of some psilocybin-containing mushrooms is that the flesh stains a bluish-green color when bruised [1]. This color change is found consistently only in some of the *Psilocybe* and *Panaeolus* spp.; it is absent in others. The reaction is thought to be related to the conversion of psilocin to a bluish pigment [41, 42]. However, blue staining with bruising is not limited to only psilocybin-containing mushrooms.

The major danger inherent in consumption of these mushrooms is misidentification and consumption of other toxic species. This danger is especially worrisome in areas where the prevalent hallucinogenic mushroom has a relatively low concentration of psilocybin, prompting consumption of many mushrooms. Examples of mushrooms similar in appearance to some *Psilocybe* spp. that have been inadvertently ingested include *Galerina autumnalis* (contains amatoxin) [39], *Cortinarius* spp. (contain orellanine) [43], *Inocybe geophylla* (contains muscarine) [44], and *Chlorophyllum molybdites* (produces gastroenteritis) [45].

Biochemistry

The pharmacologically active compounds present in these mushrooms are psilocybin (Fig. 3), a serotonin-like indole compound with similarities to LSD (lysergic acid diethylamide) and its dephosphorylated metabolite, psilocin. Both are 4-substituted tryptamine compounds; Psilocin is never found without psilocybin. Other biologic amines such as baeocystin and norbaeocystin are

Fig. 3 Chemical structure of psilocybin

also present, but their exact physiologic effects are unknown [46, 47]. Phenylethylamine, found in *P. semilanceata*, has been suggested as a cause of tachycardia and flushing; others believe that phenylethylamine is essentially inactive in humans [48, 49]. There is great variability in the interspecies concentration of psilocybin, with an average of approximately 2 mg/g of dry flesh. *Psilocybe semilanceata* often contain large amounts of psilocybin, usually greater than 10 mg/g of dried tissue [39], whereas other species may have only 0.1 mg/g. There is even a substantial difference in the content between subsequent growths (flushes) on the same culture media, a fact worth appreciating due to the common practice of *Psilocybe* cultivation [50]. Because of the great variation in psilocybin concentrations, ingestion of collected wild mushrooms may result in overdose since 20–100 mushrooms are usually eaten at one time; any one of which may have an unexpectedly large amount of psilocybin [51–53].

Psilocybin is approximately 50% absorbed orally and is rapidly dephosphorylated to psilocin [54]. Psilocin is responsible for the central nervous system effects because it is more lipid soluble and crosses the blood–brain barrier. It has an elimination half-life of about 50 min [55]. Approximately 65% of a psilocybin dose is excreted in the urine, 25% is as psilocin, and the rest as 4-hydroxyindolacetic acid and conjugated derivatives [56]. Tolerance to the hallucinogenic effects of psilocybin develops rapidly and is hypothesized to occur even during its continued absorption [52].

Psilocin is an agonist at 5HT_{2A} and 5HT_{1A} serotonin receptors in the raphe nuclei of the reticular formation, among other areas [55, 57]. This stimulation is thought to decrease negative feedback on sensory input (i.e., disinhibit), causing increased stimulation of cognitive, emotional, and visual areas [46]. The reduction in negative feedback also may contribute to (the very rarely reported) seizures and hyperthermia. The threshold dose of psilocybin is around 3–6 mg, and a dose of 8–25 mg results in the full range of clinical effects [55, 56].

Clinical Presentation

Euphoria is common, and “bad trips” (dysphoria) are the exception after the ingestion of these mushrooms; however, the latter are more common when an individual ingests psilocybin-containing mushrooms without intending to do so. Most people ingesting psilocybin-containing mushrooms never seek medical attention. The onset of effects generally occurs approximately 15–45 min after ingestion, depending on the preparation. A full stomach may delay onset. The peak hallucinogenic activity lasts approximately 1 h and usually resolves after 4–12 h [56, 58, 59]. Symptoms persisting greater than 12 h are atypical and should prompt a search for alternative explanations, although some clinical manifestations (including pupillary dilation) may persist beyond this time frame [52, 60].

Central nervous system effects of psilocybin-containing mushrooms include optical (especially faces), auditory (distortions and hallucinations), and tactile illusions, with true hallucinations occurring much less commonly [52]. Most patients remain aware that they are having altered perceptions or are hallucinating and usually remain able to engage in limited conversation [51]. The degree of perceptual alteration seems to be dose related. Depersonalization or body image distortion occurs infrequently. Racing thoughts, laughter, difficulty concentrating, and the experience of time distortions have been reported [56]. Occasional suicidal thoughts or self-harm attempts are made while suffering from psilocybin toxicity [52]. Other effects

include nausea, vomiting, abdominal pain, mydriasis, yawning, anxiety, upper trunk flushing, tachycardia, hypertension, hyperreflexia, and paresthesias, which can be unilateral and transient, involving the face and occasionally the extremities [46, 52, 53, 56, 59, 60]. Tachycardia and hypertension are probably due to agitation rather than a direct physiologic effect of psilocybin or psilocin [52, 56].

As symptoms resolve, exhaustion and depression may ensue. Mild cognitive alteration may persist for days. Persistent psychotic symptoms have been reported with repeated large ingestions, though the incidence of this is unknown. Hallucinogen-persisting perception disorder (flashbacks) has been reported [60–62]. Rare reported effects have included cerebral demyelination resulting in focal weakness, visual changes, and deafness 2 weeks after ingestion of *Psilocybe* mushrooms; rechallenge caused recurrence of symptoms and clinical findings [63].

The tachycardia and hypertension induced by psilocybin has caused paroxysmal supraventricular tachycardia and cardiac arrest in a patient with Wolff–Parkinson–White syndrome [64]. Patients with preexisting heart disease may be more likely to have ischemic injury or dysrhythmias as a consequence of ingestion of these mushrooms.

Intravenous injection of mushroom material was not reported to cause hallucinations but instead produced hyperpyrexia, rigors, hypoxemia, facial paresthesias, headache, vomiting, and myalgias. These effects are likely secondary to contaminants as these effects are not observed after injection of pure psilocybin [56, 65, 66].

Psilocybin-containing mushrooms are not hepatotoxic; however, two cases of transient elevation of aspartate transaminase, lactate dehydrogenase, and alkaline phosphatase after ingestion of *Psilocybe* and *Conocybe* mushrooms have been described; seizures were described in the same report [67]. Another case series detailed seizures in several children, with a 6-year-old developing status epilepticus and hyperthermia resulting in death. This is one of the few reported deaths directly due to psilocybin toxicity (and not secondary trauma) [68].

Diagnosis

The diagnosis of hallucinogenic mushroom poisoning is clinical and is often reasonably straightforward given the history, rapid onset of action, and physical examination findings, although other hallucinogens are occasionally substituted on purchased mushrooms. Urine assay for psilocin is not routinely available. Psilocin may be detected in urine, blood, or the mushroom itself after derivatization using gas chromatography–mass spectrometry [69, 70]. Small amounts of psilocin are excreted in the urine for days after mushroom ingestion. The presence of phenylethylamine has caused false-positive amphetamine screens using polyclonal antibodies [48]. The Meixner test, which is performed by squashing mushroom tissue against a piece of newsprint, allowing it to dry, and adding one or two drops of concentrated hydrochloric acid to the residue, will give a bluish color change for mushrooms in this class. However, this is a nonspecific test, producing indistinguishably positive results for amatoxin-containing mushrooms [71]. Identification of the mushroom through morphologic and microscopic characteristics is possible [44] but rarely clinically necessary.

Treatment

Agitated patients should be observed in a quiet, safe environment; if agitation persists, benzodiazepines are often the only further intervention required. Administration of activated charcoal has not been shown to alter outcome and is not indicated. Additionally, some patients will have vomited before presentation [58, 72]. The author recommends that neuroleptic agents should be initially avoided for theoretical reasons because their side effects may confuse the clinical picture, worsen hyperthermia, possibly potentiate the risk for hallucinogen-persisting perception disorder, and possibly increase the risk of seizures (grade III). Seizures induced by psilocybin should respond to benzodiazepines or barbiturates with careful monitoring of body temperature. If the hallucinations are causing distress for the adult patient, an oral dose of cyproheptadine could possibly diminish their intensity based on the theoretical reason that cyproheptadine, a treatment used

occasionally for serotonin toxicity, is an antagonist at serotonin 5HT_{2a} receptors, and a similar 5HT_{2a} antagonist compound, ketanserin, has been shown to limit some of the distortions and hallucinations [73, 74]. It is important to evaluate patients for injuries that may have been sustained as a result of their altered perceptual state and to monitor for evidence of hyperthermia and/or rhabdomyolysis.

Because of the short duration of effect, admission to the hospital usually is not required. Most patients are improving by the time they reach medical attention, and a short observation period in the emergency department is usually sufficient. Admission to the intensive care unit is recommended for patients who present with rhabdomyolysis, prolonged agitation, hyperthermia, seizures, or traumatic injuries. Recovery generally occurs within 12 h of presentation if psilocybin was the sole ingested toxicant. Younger children rarely may develop seizures after psilocybin ingestion and should be carefully observed [68]. Seizures are extremely rare in adults.

Hallucinogenic Mushroom Poisoning

- Includes *Psilocybe* spp. and *Panaeolus* spp.
- Toxins have similar structure to serotonin and LSD
- Meixner test may be positive but is nonspecific and will also be positive with amatoxins
- Rare seizures may be treated primarily with benzodiazepines.

Cholinergic Neurotoxic Mushroom Toxicity (Group 2B)

The muscarinic receptor agonist muscarine is found in a broad range of mushroom species, but the two genera of greatest importance are *Clitocybe* and *Inocybe*. The mushroom *Rhodophyllus rhodopolius*, found in Japan, has also been shown to contain muscarine in quantities sufficient to produce human illness [75]. Multiple other species, including *Amanita muscaria*, contain small amounts of muscarine but not enough to produce muscarine poisoning [76].

The genus *Clitocybe* includes edible species and multiple inedible muscarine-containing species, including *Clitocybe dealbata*, *C. cerrusata*, *C. rivulosa*, and *C. candicans* [1, 77, 78]. These mushrooms are found worldwide, usually growing in forests or grasslands, and may be found in fairy ring formations. The mushrooms often have white-to-brown, small, funnel-shaped caps with light-gray-, white-, or cream-colored gills. The spores are white to grayish yellow, pink, or violet. The flesh may have a pleasant/mealy smell, although this varies with the species [79]. No veil or ring is present. There are substantial differences in morphology among species [1].

The genus *Inocybe* includes many different species, and most contain muscarine [78, 80, 81]. These mushrooms are found worldwide and usually grow in soil under trees. The conical caps have a surface pattern similar to a bicycle wheel with streaks radiating from the center. Gills are light when young and become brown at maturity. The spores are brown to yellowish brown. The flesh has an earthy to unpleasant smell. The veil is fragile. There are minor differences in morphology among species [1].

Biochemistry

Muscarine is a quaternary ammonium compound (Fig. 4). Four stereoisomers are found in nature, but only L-(+)-muscarine has significant physiologic activity [46, 77]. Muscarine is not degraded by boiling or peptic digestion [82]. It is usually found in concentrations of 0.1–0.3% dry weight in

Fig. 4 Chemical structures showing homology between muscarine (top) and acetylcholine (bottom)

Inocybe and *Clitocybe* spp., but the amount may vary by up to three orders of magnitude among species [77, 80, 81]. Its gastrointestinal absorption appears to be limited and erratic. The median lethal dose in humans is unknown but has been suggested to be around 200 mg [82, 83]. Muscarine has specific agonist activity at acetylcholine muscarinic receptors, a property used experimentally to define these receptors. This agonism produces a cholinergic muscarinic syndrome. As a result of its positive charge, muscarine has limited ability to cross the blood–brain barrier, and its toxicity is limited to peripheral effects [76]. Muscarine has no affinity for, and is not metabolized by, acetylcholinesterase [76]. Some muscarine is renally excreted and may be detectable in urine [84].

Clinical Presentation

Symptoms from ingestion of muscarine-containing mushrooms are primarily cholinergic and typically begin 0.5–2.5 h after ingestion. Among the various mushroom poisonings, the constellation of signs that are characteristic of muscarine intoxication are lacrimation, perspiration, and salivation. Other commonly reported clinical manifestations are nausea and vomiting (seen in nearly all patients), abdominal pain, anxiety, wheezing, headache, fatigue, chills, perioral paresthesias, diplopia, urinary urgency, and diarrhea [85]. Muscarine-intoxicated patients occasionally are bradycardic and hypotensive and have miotic pupils. These effects usually last approximately 2 h; although untreated, they may persist for up to 24 h [78, 86].

The clinical presentation of muscarine poisoning is similar to that of some other mushroom ingestions, such as the gastrointestinal irritants; however, the triad of perspiration, salivation, and lacrimation also is seen. Central nervous system effects, such as confusion, vertigo, and hallucinations are not expected because muscarine does not cross the blood–brain barrier. If patients are confused, they may have ingested a mushroom with centrally active compounds, such as ibotenic acid from central nervous system toxicity group of neurotoxic mushrooms Group 2C, or alternatively are dehydrated from vomiting and diarrhea. It is

unproven, but suspected, that there are mushrooms containing muscarine and ibotenic acid that produce a mixed clinical picture of cholinergic and central nervous system effects [85].

Diagnosis

The diagnosis of muscarinic mushroom ingestion is clinical, based on the time course of the signs and symptoms and the description or identification of the ingested mushrooms. There is often difficulty differentiating gastrointestinal irritant mushroom poisoning from this group. With a mushroom sample, testing for muscarine can be performed with liquid chromatography [81], although this is not commonly done in a clinical setting. Gas chromatographic methods are technically difficult and are not commonly performed [87].

Treatment

Muscarine is one of the few toxins that has an almost perfect antidote. Atropine was recommended in the past to reverse muscarinic cholinergic effects based on both mechanistic reasons and case reports. Most references recommend sequential intravenous doses of 0.1 mg in adults and 0.02 mg/kg in children (minimum 0.1 mg per dose) (grade III evidence). The goal of treatment is symptom resolution; however, atropine is not an ideal antidote because it crosses the blood–brain barrier and may cause central anticholinergic effects. Although not studied, glycopyrrolate is a more selective antidote and may have an advantage over atropine. It antagonizes peripheral acetylcholine muscarinic receptors, but being a quaternary amine, it does not penetrate the blood–brain barrier. Sequential glycopyrrolate intravenous doses of 0.1 mg in adults and 0.005 mg/kg in children appear to be safe [88] (grade III evidence). When patients present with significant bronchospasm, inhaled ipratropium, an anticholinergic quaternary amine that has limited systemic absorption, could be utilized, based entirely on its mechanism of action (grade III evidence).

Intravenous volume replacement may be required if patients are significantly volume depleted from vomiting and diarrhea. Fluids may

help correct hypotension. An unclear diagnosis or significant clinical manifestations are indications for hospital admission. Mildly symptomatic or asymptomatic patients may be discharged from the emergency department after a period of observation and clinical recovery, provided that there is assurance that the patient has not ingested a more toxic mushroom. The possibility of a mixed-mushroom ingestion always should be considered, and close follow-up should be ensured.

Children and elderly individuals are at increased risk of dehydration from the cholinergic effects of muscarine. A more prolonged period of observation is warranted for these populations to ensure that there is no recurrence. It is unknown whether muscarine crosses the placenta. Data are limited regarding the safety of glycopyrrolate in pregnancy, but it has significantly less placental transfer than atropine and does not alter fetal hemodynamics [83].

Cholinergic Neurotoxic Mushroom Toxicity

- Muscarine-containing mushrooms
- Includes *Clitocybe* spp. and *Inocybe* spp.
- Agonists at acetylcholine muscarinic receptors
- Antidote is atropine or possibly glycopyrrolate

Central Nervous System Mushroom Toxicity (Group 2C)

Ibotenic acid and muscimol are structurally related isoxazole compounds present in certain *Amanita* spp. These substances are known for their sensorium-altering effects. Hundreds of years ago, Siberian and Eskimo tribes ingested these mushrooms for their intoxicating properties; the urine from intoxicated individuals was also consumed to cause inebriation [89]. The most important mushrooms containing ibotenic acid and muscimol are *A. muscaria* and *A. pantherina*; of note, subspecies of both with subtle morphological differences are known to exist [90–92].

Amanita muscaria (“fly agaric”) is found worldwide, except in the tropics, often growing under trees such as pine, beech, and aspen. It is the

classic mushroom often pictured in fairy tales (and video games), with a distinctive cap having a color ranging from red to orange, yellow, or white; the color may fade with age (Fig. 5). The cap, about 7–15 cm in diameter, is covered with pale yellow-to-white spots or warts. The stalk is white with a persistent membranous ring; the gills and spores are also white. The volva tissue is intergrown with

Fig. 5 *Amanita muscaria* (From Schneider S, Donnelly M: Mushroom toxicity. In Auerbach PS [ed]: Wilderness Medicine, 4th ed. Philadelphia, Mosby, 2001, p 1148, with permission)

the bulb, and there are characteristic rings along the volva from the universal veil [1].

Amanita pantherina (“panther mushroom”) has a brown-to-dull yellow cap about 5–12 cm in diameter with white or yellow warts. It grows alone or in small groups and commonly is found under conifers. It has a white stalk with a white membranous ring, pale gills, and white spores [1]. Generally, *A. pantherina* has greater concentrations of ibotenic acid and muscimol toxins than does *A. muscaria* [90].

Biochemistry

Ibotenic acid and muscimol are false neurotransmitters; their structures are similar to the excitatory neurotransmitter glutamate and the inhibitory neurotransmitter γ -aminobutyric acid (GABA) (Fig. 6), respectively. The major structural difference between the mushroom toxins and the true neurotransmitters is the presence of an isoxazole ring involving the terminal carboxylic acid residue on the former. In contrast to their true neurotransmitter counterparts, ibotenic acid and muscimol readily cross the blood–brain barrier, producing inebriation.

Muscimol is an agonist at GABA-A receptors [93]. This GABAergic activity is likely responsible for the somnolence and inebriation seen in poisoning by mushrooms in this group. Ibotenic acid is an

Fig. 6 Comparison of isoxazole toxins with endogenous neurotransmitter structures and metabolic pathways

agonist at N-methyl-D-aspartate–glutamate receptors, causing neuronal excitation. Ibotenic acid is decarboxylated to muscimol in a manner analogous to the enzymatic conversion of glutamate to GABA. The decarboxylation of ibotenic acid is spontaneous, whereas the conversion of glutamate to GABA requires glutamate decarboxylase (see Fig. 6).

Ibotenic acid and muscimol are not effectively removed from the neuronal synapse by the uptake systems that remove glutamate and GABA. About one third of the muscimol and almost all of the ibotenic acid absorbed after mushroom ingestion is excreted unchanged in the urine, with peak excretion of ibotenic acid occurring within 60 min. The remainder of muscimol is excreted as oxidative and conjugated metabolites [94].

Ibotenic acid and muscimol are present in roughly equal quantities at concentrations between 0.03% and 0.5% in relevant *Amanita* spp., [90, 94]. The total toxin content varies greatly even among mushrooms of the same species, collected at the same time, from the same area [95]. Their toxicity also depends on growth substrates, methods of preparation, and length of storage before use. Ibotenic acid is spontaneously converted to muscimol. Because ibotenic acid is much less potent than muscimol, drying the mushroom increases the muscimol content and, therefore, the potency. The yellow pigments of *A. muscaria* have been shown to possess a significantly larger amount of ibotenic acid than the rest of the mushroom. Although it is not recommended, people do eat *A. muscaria* after peeling off the skin and parboiling.

The median lethal dose of muscimol varies greatly in rats but is approximately 25 mg/kg. It is unusual for humans to ingest enough *A. muscaria* to cause death. Human toxicity usually occurs with ingestion of 6 mg of muscimol, or two to four mushrooms, but even a single mushroom has produced toxicity [95].

Clinical Presentation

Signs and symptoms begin 0.5–2 h after ingestion [95]. Experimentally, clinical manifestations begin within 1 h of ingestion of 10 mg of

muscimol or 75 mg of ibotenic acid. Symptoms consist of nausea and vomiting (in about half of the patients), diarrhea, cramps, increased reflexes, tremor, myoclonic jerking, fasciculations, ataxia, extremity paresthesias, incoordination, visual changes, and altered mental status [92, 95]. The pupillary response is variable. The skin has been described as flushed and diaphoretic. Respiratory depression, bradycardia, and hypotension are rarely reported. Seizures rarely occur but may be more common in children [95]. Deaths have been reported after large ingestions (>10 mushrooms) or in association with comorbidities [96].

The usual clinical presentation of toxicity by these mushrooms is an altered mental status or inebriation, without airway compromise. The clinical course is characterized by a waxing and waning sensorium, alternating between agitation and obtundation. This effect is especially pronounced in children. Patients often exhibit bizarre behavior – elation with disorientation, depersonalization, and increased motor activity [95]. Perceptual illusions are common [97]. As the effects resolve, lethargy usually develops followed by deep protracted sleep. Patients are often amnesic to events occurring during intoxication.

Occasionally, patients exhibit muscarinic-like symptoms, including salivation, bradycardia, perspiration, vomiting, and diarrhea [95]. It is not known whether these symptoms are due to the isoxazoles, to the presence of abnormally large amounts of muscarine [89], or to an unidentified compound [92]. Most patients have improvement of symptoms within 8 h, with major toxic effects lasting approximately 12 h [95]. Residual symptoms of headache, paresthesias, and fatigue occasionally are reported for as long as 48 h afterwards [97–99].

Diagnosis

No specific laboratory tests are required. Identification of the offending mushroom and its associated toxic syndrome is usually based on the description of the mushroom as it has distinctive morphological characteristics and the patient's clinical presentation. These mushrooms are not illegal and are occasionally ordered online, in

which case they will be dried and somewhat harder to identify.

Treatment

Treatment of central nervous system toxic mushroom poisoning is primarily supportive, with symptomatic patients requiring observation in a quiet environment. Most clinical toxicologists recommend that the patient be observed until the clinical manifestations resolve. Severely intoxicated patients may require admission to the intensive care unit (see the earlier box on “Indications for ICU Admission in Mushroom Poisoning”). Patients poisoned with these mushrooms require monitoring for seizures, central nervous system depression, and aspiration. Early administration of activated charcoal may decrease absorption, but the risk of aspiration may outweigh its theoretical benefits, especially if significant time has passed after ingestion (grade III evidence). Carefully titrated benzodiazepines are indicated to control agitation and seizures. The respiratory depressant effect of benzodiazepines is potentially increased with muscimol intoxication; small, incremental doses should be used to prevent apnea [97]. Volume replacement is indicated for patients with significant gastrointestinal losses or hypotension, with vasoactive agents reserved for hypotension refractory to fluid resuscitation.

Although these patients may manifest features similar to cholinergic or anticholinergic toxidromes, muscimol and ibotenic acid do not have significant activity at the muscarinic receptors, and therefore there is no role for either atropine or physostigmine. For a mixed ingestion that included a cholinergic mushroom, glycopyrrolate may be used instead of atropine because the former does not alter mental status; however, this has not been formally studied.

Seizures are much more likely to occur in children [95]. Mortality increases with age and the presence of significant comorbidities, including coronary artery disease and chronic obstructive pulmonary disease. There should be a reduced threshold for admission to the intensive care unit for these patients. There are no data relating to isoxazole-containing mushroom toxicity in pregnancy.

Central Nervous System Mushroom Toxicity

- Ibotenic acid/muscimol-containing mushrooms
- Includes *Amanita muscaria* and *Amanita pantherina*
- Inebriating mushrooms
- Toxins have similar structures to glutamate and γ -aminobutyric acid (GABA)
- Rare seizures may be treated with benzodiazepines

Morel Neurologic Syndrome (Group 2D)

Consumption of morels (*Morchella*) can rarely cause a syndrome of gastrointestinal and/or neurologic symptoms [100]. Illness usually occurs only when they are ingested raw or undercooked, but symptoms have also occurred after eating cooked morels. Gastrointestinal symptoms usually begin about 5 h (2–12 h being the usual range) after ingestion with longer delays possible. Reported gastrointestinal symptoms include nausea, vomiting, diarrhea, and abdominal pain. Neurological symptoms usually begin about 12 h after ingestion, although delays up to 36 h have been reported. Symptoms include changes in vision, headache, paresthesia, ataxia, tremor, and drowsiness [101]. Other reported symptoms after consumption of morels include asthenia, sweating, and syncope. Treatment is supportive, and recovery occurs in nearly all patients within about a day [100, 101].

Myotoxic Mushroom Toxicity (Group 3)

Rhabdomyolysis induced by mushroom ingestion has only recently been reported, and human experience is somewhat limited.

Rapid onset myotoxicity (group 3A) is caused by the mushroom *Russula subnigricans*. It was reported to cause nausea, vomiting, and diarrhea

within 2 h of a single ingestion in nine patients. In most of these patients, symptoms were self-limited and resolved within 1 day, but two patients became progressively more ill. They developed muscle pain, weakness, dark urine, and rhabdomyolysis. One required dialysis; both survived, although one had an elevated creatinine on discharge (day 33) [102]. The toxin responsible in *R. subnigricans* is believed to be cycloprop-2-ene carboxylic acid [103].

Delayed onset myotoxicity (group 3B) has been caused by the mushroom *Tricholoma equestre* (or yellow-knight fungus). In one case series, this mushroom was ingested for at least three consecutive meals in 12 patients. They did not experience gastrointestinal symptoms but developed fatigue, myalgias, nausea, and dark urine associated with rhabdomyolysis 1–3 days after their last meal. Three of these patients developed increasing dyspnea at rest, myocarditis, acidosis, and renal failure and died despite aggressive intensive care unit support which included veno-venous hemofiltration in one case [104].

Treatment of toxicity from myotoxic mushrooms centers on recognition and early aggressive care. Decontamination will not have a role due to the unlikelihood of presentation early after ingestion. As rhabdomyolysis is a component of both, IV fluid hydration along with supportive critical care possibly including hemodialysis will be required.

Metabolic Pathway Toxicity (Group 4)

This group contains mushrooms with diverse effects on human physiology with the common thread being changes to various specific biochemical pathways. ► [Chapter 109, “Gyromitra mushrooms”](#) discusses the group causing GABA deficiency and seizures (group 4A). This chapter will discuss disulfiram-like metabolic mushroom toxicity in detail (group 4B), but there are a few other very rarely encountered syndromes in this group.

Polyporic mushroom toxicity is caused by ingestion of *Hapalopilus rutilans* (group 4C). Onset is several hours of ingestion, and clinical

effects include purple urine, nausea, vomiting, nystagmus, cerebral edema, and hepato-renal failure [105]. It is one of the very few specific (i.e. not just simple GI irritation) mushroom poisoning syndromes caused by a polypore (i.e., not a gilled mushroom). The addition of 3% potassium hydroxide to the mushroom will result in a deep violet color [106]. The treatment for this extremely rare syndrome is supportive.

Hypoglycemic mushroom poisoning (group 4E) is caused by a newly discovered Chinese mushroom *Trogia venenata* which has resulted in sudden death hours to days after ingesting meal-sized amounts [107, 108]; the mushroom is geographically restricted to one province in China (northern Yunnan).

Trichothecene mushroom poisoning (group 4D; *Podostroma cornu-damae*) is limited to Japan, Java, and Korea where the relatively rare mushroom is found. Ingestion of even small amounts of mushroom results in vomiting, diarrhea, dehydration, hypotension, acute renal injury, lethargy, hepatic necrosis, DIC, and death. With survival beyond a few days, hair loss, desquamation, pancytopenia, and cerebellar atrophy have been reported. Treatment is supportive [109, 110].

Other reported mushroom poisoning syndromes proposed to be included within this group are hyperprolactinemia mushroom poisoning (group 4F; *Boletus satanas* or *Rubroboletus satanas*) and pancytopenia mushroom poisoning (group 4G; *Ganoderma neojaponicum*) [2].

Disulfiram-Like Metabolic Mushroom Toxicity (Group 4B)

The disulfiram-like toxicity from *Coprinus* mushrooms occurs only with temporally proximate co-ingestion of ethanol [111–113]. *Coprinus atramentarius* is known as the “inky cap” because at maturity the cap and gills autodigest, or deliquesce, into a black, ink-like liquid. The mature mushroom has a gray-to-brown, bell-shaped cap 4–6 cm across, with small brown scales or fibrils located primarily in the center of the cap. The stalk, white above the ring and gray below, is

slender with a hollow center and false ring. The gills are crowded, and the spores are black to brown-black. The mushrooms are widely distributed in the fall and spring, usually growing in clumps at the base of trees or over buried wood [1].

Biochemistry and Pathophysiology

Coprinus atramentarius contains the nonessential amino acid coprine (N5-[1-hydroxycyclopropyl]-L-glutamine) (Fig. 7) [114, 115]. Coprine has been found in several other *Coprinus* spp. that are too tiny to be eaten in clinically significant amounts [116]. Other mushroom genera have been reported to produce similar symptoms when combined with ethanol, but none have been found to contain coprine; symptoms may be due to ethanol and a concomitantly ingested gastrointestinal irritant mushroom or other systemic illness [120]. Cooking does not generally change the concentration of coprine significantly [114, 116]. However, there are reports that cooking may increase toxicity [117].

Coprine is a protoxin that is metabolized to the active toxin, 1-aminocyclopropanol (ACP) after ingestion. 1-Aminocyclopropanol inhibits the activity of aldehyde dehydrogenase, the primary enzyme required for the metabolism of the ethanol metabolite acetaldehyde to acetate [112, 118, 119]. 1-Aminocyclopropanol irreversibly inactivates aldehyde dehydrogenase by forming a covalent bond with the active site, resulting in an accumulation of acetaldehyde, which is thought to contribute to the disulfiram-like syndrome [116, 118, 120, 121].

Although clinically similar to disulfiram, coprine does have some important differences. It is an alkylating agent and has been shown to be mutagenic and to cause bone marrow depression in dogs [122]. These actions are unlikely to be of clinical significance for the occasional human ingester of coprine-containing mushrooms. Coprine

appears to be a more potent inhibitor of aldehyde dehydrogenase than disulfiram. In contrast to disulfiram, coprine does not inhibit dopamine β -hydroxylase, the enzyme responsible for norepinephrine synthesis [121, 123].

Clinical Presentation

The disulfiram-like reaction that occurs after coprine mushroom ingestion promptly occurs when ethanol is consumed within 24–48 h of eating the mushroom meal [116, 117, 124]. Symptoms can recur if alcohol is consumed again within 72 h after mushroom ingestion [116]. The intensity of the reaction is related to the timing and quantity of the mushrooms and the ethanol ingested. The reaction is more pronounced if ethanol is consumed several hours after the mushrooms are consumed rather than at the same time [125]. Typical symptoms occur within a few minutes of the ethanol ingestion. Facial flushing, a blotchy, erythematous rash extending over the arms and chest, dyspnea, headache, metallic taste, diaphoresis, nausea and vomiting, tachycardia, premature ventricular contractions, atrial fibrillation, hypotension, hypothermia, vertigo, confusion, and coma may occur [126–128]. Esophageal rupture is a reported complication of the forceful emesis that can occur [127]. Coprine/ethanol reactions typically cause more tachycardia than disulfiram/ethanol interactions [123]. Symptoms usually last 30 min to a few hours. Recovery usually occurs within 24 h even when reactions are severe [113, 116, 126].

Diagnosis

A history of mushroom and ethanol ingestion followed by a rapid onset of a disulfiram-like reaction described above is diagnostic. A careful history eliciting any other exposures capable of producing a disulfiram-like reaction should be obtained (e.g., metronidazole, trichloroethylene,

Fig. 7 Chemical structure of coprine (left) and conversion to the metabolite, 1-aminocyclopropanol

disulfiram). A serum ethanol assay may be obtained if confirmation of alcohol ingestion is warranted.

Treatment

Treatment is primarily symptomatic and supportive. There is no role for gastrointestinal decontamination. There is no evidence that antihistamines reduce the flushing associated with this poisoning. Propranolol has been proposed to treat the tachycardia; however, this has not been studied and may be risky in patients who are seriously ill [129]. Because the clinical effects are caused by acetaldehyde accumulation, an alcohol dehydrogenase inhibitor, such as fomepizole, administered while blood ethanol concentrations are elevated could theoretically reduce the severity of the symptoms by limiting acetaldehyde production; this, too, has not been studied. Hypotension occasionally occurs and usually responds to fluids but may require intravenous pressor agents. As noted above, in contrast to disulfiram, there is no inhibition of dopamine β -hydroxylase by coprine or its metabolites, and therefore dopamine could be effective based on mechanistic reasons [123]. However, other pressors, such as norepinephrine, may be preferable. The pressor of choice, to the extent that one is needed, has not been studied.

If the patient is critically ill, hemodialysis theoretically could be used to remove ethanol and acetaldehyde; however, this treatment would not be expected to limit the effects of coprine because at the time of dialysis the patient already would have undergone significant irreversible inhibition of aldehyde dehydrogenase; this has not been studied. The administration of any ethanol-containing preparation or product should be avoided for at least 72 h after ingestion of coprine-containing mushrooms.

The scenario of co-ingestion of mushrooms and ethanol is unlikely in children. Fomepizole has not been evaluated in pregnancy [130]. The elderly are more likely to have greater morbidity from a coprine-ethanol reaction, especially elderly individuals with cardiovascular disease or those who would have greater morbidity from the vomiting. Treatment for these groups is as outlined earlier.

Disulfuram-Like Mushroom Toxicity

- *Coprinus* mushrooms
- Contains a protoxin
- Produces a disulfiram-like reaction with concurrent or delayed ethanol consumption
- The Alcohol dehydrogenase inhibitor fomepizole could be beneficial in selected cases

Gastrointestinal Irritant Mushrooms (Group 5)

Gastrointestinal irritant mushrooms are the largest and least well-defined group of mushrooms; there are hundreds of species that produce primary gastrointestinal irritation. The toxins responsible for gastrointestinal irritation are varied and in many cases have not been identified. There is great individual variability in response to these toxins. Some people become very ill after ingestion; others do not become ill at all [131]. Clinical onset of nausea, vomiting, or diarrhea occurs within several hours after ingestion, an important distinguishing feature that can assist in differentiation from other more dangerous ingestions such as the hepatotoxic (amatoxin-containing) mushrooms, unless a co-ingestion of multiple mushroom types has occurred. With some very rare exceptions, toxicity arising from ingestion of a polypore (i.e., mushrooms that have pores and not gills) or puffball will be limited to gastrointestinal irritant toxicity.

Generally, only supportive care is required. There is no role for gastrointestinal decontamination; activated charcoal is unlikely to be of clinical benefit. Significant electrolyte disturbances and volume depletion with hypotension may occur. Children and the elderly are more likely to require medical treatment and admission to the hospital. Treatment consists of intravenous hydration, electrolyte supplementation, and antiemetic therapy. An antiemetic 5-HT₃ receptor agonist, such as ondansetron, is theoretically preferred to a phenothiazine, which may have side effects such as sedation that could be mistaken for a component of mushroom toxicity (grade III recommendation). The possibility of concomitant

ingestion of a cytotoxic mushroom should always be considered, and close follow-up is essential. Two mushroom species that will be discussed due to their prevalence and common misidentification are the jack-o-lantern mushroom and *Chlorophyllum molybdites*.

Jack-o-lantern Mushroom: *Omphalotus olearius/illudens*

The jack-o-lantern mushroom is an orange mushroom usually with bold color that grows in groups with non-forking faintly bioluminescent gills; it is occasionally mistaken for chanterelles. The toxin responsible for the gastrointestinal illness is believed to be the sesquiterpene illudin [132]. It has sometimes been incorrectly classified as a muscarine-containing mushroom [133]. The symptoms of abdominal pain, diarrhea, vomiting, rarely sweating, dry mouth or salivation, weakness, and visual changes may be similar to the cholinergic (muscarinic) toxicity mushrooms, but patients do not consistently report the cholinergic symptoms of salivation and lacrimation [134–136]. European reports of toxicity describe a more severe syndrome than that seen in North America including elevated transaminases, vertigo, salivation, diplopia, and fatigue with prolonged duration of illness (5–6 days) [135–137].

Green-Spored Parasol: *Chlorophyllum molybdites*

Chlorophyllum molybdites has worldwide distribution and is commonly found on lawns, occasionally growing in fairy rings; the reader is highly likely to already have seen this mushroom. The mature mushroom has a large white cap 7–30 cm in diameter that is covered with scales, frequently with a hint of pink-to-brown color at the center of the cap and scale tips. The stalk is smooth, tall (10–15 cm), and slender (2–2.5 cm at apex, 4–6 cm at base) with a thick ring. The flesh has a pleasant taste. The gills are pale yellow when young, turning green with age. The spore

Fig. 8 *Chlorophyllum molybdites* spore print

print is a distinctive green color that can be helpful in identification (Fig. 8) [1].

The toxins have not been isolated. Cooking may reduce the potency of the toxins but does not render the mushroom edible.

A few people remain asymptomatic after ingesting *Chlorophyllum* mushrooms, an observation that is consistent with individual variation in response to the toxin. Ingestion of a portion of a single mushroom generally rapidly produces nausea and vomiting within 1–2 h of ingestion and rarely beyond that time limit. Vomiting is copious. Diarrhea also is common, and often explosive, and can be heme positive. Other symptoms commonly reported are diaphoresis, chills, dizziness, and abdominal pain [138–140]. Hypovolemia and electrolyte disturbances from the gastrointestinal losses may be severe and accompanied by other complications (e.g., seizures) if not treated. Gastrointestinal bleeding associated with disseminated intravascular coagulation has been rarely reported [141]. *Chlorophyllum molybdites* ingestion has not been reported to cause hepatic or renal injury.

Most patients improve within 4–6 h, but severely poisoned patients may not improve for 2–3 days. Patients with diarrhea and vomiting should be observed until symptoms subside.

Patients should be monitored closely for laboratory evidence of fluid or electrolyte depletion. Typing and screening for blood is recommended for patients with evidence of significant bleeding. Patients with refractory vomiting or bloody diarrhea should be admitted to the hospital. Fluid losses can be severe, necessitating several liters of intravenous fluid replacement in adults; vasopressors may be used if the patient continues to be hypotensive after adequate resuscitation. Invasive monitoring may be employed to guide treatment, if needed [140]. Deaths have occurred in pediatric patients, and intubation has been required [140]. Intensive care unit admission is warranted for children, elderly individuals, patients with significant fluid losses, and patients with significant comorbidities [140].

Analysis of the vomitus or stool may be done to determine the presence of *Chlorophyllum* spores [142]. The green spore print is nearly pathognomonic for *Chlorophyllum*.

Gastrointestinal Irritant Mushroom Poisoning

- Includes *Omphalotus olearius* and *Chlorophyllum molybdites* and many others
- Intravenous hydration may be necessary depending on the amount ingested and comorbidities

Miscellaneous Adverse Reactions (Group 6)

This group contains mushrooms that occasionally cause a variety of clinical effects which, excepting *Paxillus* syndrome, are not often life threatening or are extremely rare and geographically limited.

Shiitake Dermatitis (Group 6A)

The ingestion of raw or undercooked shiitake mushrooms can result in a distinctive dermatitis called shiitake dermatitis or “flagellate erythema” named after markings caused by self-flagellation [143]. The rash is pruritic, made of small (≈ 1 mm)

erythematous papules usually organized as linear streaks always found on the trunk but also potentially on the extremities, neck, face, and head. The rash is on areas the patient can reach and does not involve the mucosal surfaces; there is a photosensitivity component of the rash [144, 145]. It appears usually within 0.5–2 days of mushroom ingestion [145, 146]. The responsible toxin is believed to be the thermolabile polysaccharide lentinan [146, 147]. Histological changes are nonspecific, and diagnosis is by history and clinical presentation; there is no role for patch testing. Treatment recommendations are based on case level evidence (grade III); avoiding sun exposure combined with use of antihistamines provides some mild pruritus relief. Improvement is usually complete within 2 days to 2 weeks, with one outlier in a series having symptoms for 38 days [145, 146].

Erythromelalgic Syndrome (Group 6B)

The erythromelalgic syndrome (some have suggested acromelalgia syndrome) is usually reported in Japan but has been recently reported in Europe. The causative mushroom is *Clitocybe acromelalga* (known as “Dokugasako” in Japan; the mushroom is also found in Korea), but *C. amoenolens*, found in Europe, also likely causes this syndrome [148, 149]. The neuroexcitatory toxins responsible are acromelic acids, heat-stable potent analogues of the glutamate agonist, kainic acid [150–152]. The major symptom is pain in the extremities, beginning usually one to a few days after ingestion. The pain is described as a burning or electric shock-like pain which has an intermittent nature, lasting several hours with episodes occurring more at night. The pain can be made worse by even a simple light touch [153]. During episodes, there may be edema and erythema of the distal extremities. Other reported symptoms include paresthesias of the extremities and fatigue. This paroxysmal extremity pain may persist for weeks to months. Treatment is supportive, with some possible relief with short cold-water immersion, taking care to avoid injury from excessive

exposure (grade III evidence). Pharmaceutical treatment of the pain is often not effective, but acetylsalicylic acid, clomipramine, and morphine have been used with minimal success [149]. Treatment with IV (20 mg/day up to 100 mg/day for 7 days) and PO nicotinic acid (100 mg/day, slowly decreased and stopped after 3 months) has been used successfully in one case; the mechanism behind this might be due to vasodilatation or effects on metabolism [153] (grade III). As acromelic acids augment glutamate-induced depolarization, a possibility based entirely on mechanism of action might be seen with agents which inhibit glutaminergic transmission, such as topiramate [152, 154] (grade III).

Paxillus Syndrome (Group 6C)

Ingestion of *Paxillus involutus*, also known as “brown roll-rim,” can cause a severe immunologically based hemolytic illness known as *Paxillus* syndrome. This is a common mushroom illness reported in Europe [155]. Upon ingesting the mushroom (raw or cooked), an individual is exposed to the antigens; this first time they may or may not have mild symptoms (nausea, dizziness). The identity of these antigens is unknown. When ingested a second time, they absorb these antigens that form immune complexes which attach to the surface of erythrocytes. This results in agglutination and hemolysis [155, 156]. Some have suggested there may be another component of the illness caused by a direct cytotoxic compound [155]. Symptoms usually begin within 30 min to 2 h. Abdominal pain, back pain, dizziness, vomiting, and diarrhea are associated with hypotension, hemoglobinuria, oliguria/anuria, and mild jaundice [155, 157]. Patients can develop hemolysis, hyperkalemia, hypotension/shock, renal failure, and DIC. *Paxillus* syndrome has been fatal [156]. The diagnosis is clinical; a hemagglutination reaction against a *Paxillus* extract has been demonstrated in serum from some patients but this test is not commonly available. Treatment is supportive, with plasma exchange used in a few cases and hemodialysis required for those with renal injury [157].

Encephalopathy Syndrome (Group 6D)

The encephalopathy syndrome is from ingestion of the once believed edible mushroom, *Pleurocybella porrigens* (sugihiratake mushrooms). Cases of toxicity are extremely rare and limited to Japan where only a few cases have been reported. This syndrome appears to require that patients have some degree of preexisting renal insufficiency. The onset of the clinical syndrome occurs several days after ingestion of the mushroom and is marked by weakness, dysarthria, coma, seizures, and death; the mortality is around 30% [158, 159].

In contrast to many of the man-made toxins found in the world today, the toxins present in amanitin-containing mushrooms probably have been afflicting humans for as long as they have been picking mushrooms from their varied habitats and consuming them as a readily available and tasty food source. Among all poisonous mushrooms, the widely distributed green death cap (Fig. 1), *Amanita phalloides*, may have played the leading role, having been recognized as poisonous mostly by trial and error.

Traditional treatments have been primarily based on anecdotal evidence. One of the treatments for amanitin poisoning that evolved in the 1800s and lasted until the 1930s was based on the observation that rabbits consumed these mushrooms with impunity. This led to the development of an antidote consisting of the stomachs of three rabbits and the brains of seven rabbits, with addition of sweeteners for palatability. The ingredients were finely chopped to mask their origins. Because many individuals who received this regimen survived – most probably those suffering from a less severe intoxication – the use of this remedy persisted for many years [1]. Another anecdotally touted antidote for amanitin poisoning was a cocktail proposed by Pierre Bastien, a practitioner from Alsace, which contained vitamin C, vitamin B, nifuroxazide, and neomycin. With this regime he survived several experiments on himself [2].

At the beginning of the last century, the mortality rate of amanitin poisoning was very high.

Alder published a paper [3] in which he mentioned mortality rates at the beginning of the twentieth century. In 1905 and 1913, the rate was 63%/52% in France, 46% in Germany between 1914 and 1923, and 45% in France between 1921 and 1928. Nowadays the mortality rate is down to 5–10% most likely due to the improvement of intensive care and the introduction of a variety of antidotes as described below.

Mushrooms that contain amatoxins are largely from three genera: *Amanita*, *Galerina*, and *Lepiota* species. Amanitin-containing mushrooms are probably responsible for more than 95% of mushroom fatalities worldwide [4]. It can be confused with other green mushrooms such as *Russula cyanoxantha*, *Russula virescens*, and *Tricholoma flavovirens* [5]. Other *Amanita* spp. that contain amatoxins include *Amanita ocreata*, *Amanita verna*, *Amanita bisporigera* [6], and *Amanita virosa* (destroying angel). *Amanita virosa* and *Amanita verna* can be mistaken for *Agaricus campestris*, *Agaricus sylvaticus*, and

Agaricus abruptibulbus [5]. *Amanita* mushrooms are usually large in size and often fruit in sufficient numbers to invite picking. *A. phalloides* bears enough resemblance to a widely cultivated mushroom of southern Asia, *Volvariella volvacea* (paddy straw mushroom) that groups of immigrants in California, Oregon, and New York have mistakenly harvested and been poisoned by them. Nontoxic *Amanita* spp., including *Amanita caesarea*, *Amanita rubescens* (blusher), *Amanita calypttrata*, and *Amanita velosa*, are sought by knowledgeable collectors for their fine taste [6]. Two other *Amanita* spp., *Amanita pantherina* and *Amanita muscaria* (fly agaric), do not contain cyclopeptides but are toxic due to the presence of ibotenic acid, causing transient syndromes primarily involving the central nervous system.

Galerina spp., another amatoxin-containing genus, are small brown mushrooms growing on decaying wood. Because *Galerina* mushrooms may be mistaken for hallucinogenic *Psilocybe* mushrooms, misidentification between these genera may lead to amatoxin poisoning. Especially *Galerina marginata* can be mistaken for *Kuehneromyces mutabilis* [7] or *Armillaria mellea* (honey-colored agaric). Further amatoxin-containing *Galerina* spp. include *Galerina autumnalis* and *Galerina venenata*. Some samples of *Conocybe filaris* also have been shown to contain the toxin [1]. Certain *Lepiota* spp. also contain amatoxins: *L. helveola*, *L. fulvella*, *L. josserandii*, and *L. brunneoincarnata*. *Lepiota* mushrooms are small and may be confused by the indiscriminate picker with larger *Lepiota* spp. as parasol mushroom (*L. procera*) and *L. rhacodes* [8] (Table 1).

Chemistry of Amanitin/Amatoxins

Alpha-Amanitin (Fig. 2) was first isolated from the mushroom *A. phalloides* in 1940 at the Ludwig Maximilian University in Munich by Heinrich Wieland and Hallermayer [12]. Its structure is an octapeptide and was elucidated in 1966 by Theodor Wieland and Gebert [13], the complete formula by Faulstich et al. 2 years later

Table 1 Concentrations of amatoxins (mg/g dry weight) in amatoxin-containing mushrooms. Assumed deadly dose: 0.1 mg/kg bw [9–11]

Mushroom	Amatoxins (mg/g dry weight)
<i>Amanita phalloides</i> A.var. <i>verna</i> and <i>Amanita</i>	1.4–6.8
<i>Amanita virosa</i>	1.9–2.6
<i>Lepiota brunneoincarnata</i>	1.3
<i>Lepiota josserandii</i>	3.5
<i>Galerina marginata</i>	0.6

[14]. Today we know a group of nine thermostable cyclic peptides of this kind called the amatoxin family, with α - and β -amanitin constituting about 90% of all. Amatoxins are cyclic octapeptides. The molecule adopts a double-ring structure because of the sulfoxide bridge between the side chains of the two juxtaposed amino acids in the cyclic peptide, cysteine and hydroxytryptophan. Amatoxins vary in the extent of hydroxylation in one of the isoleucine side chains or in replacement of asparagine for aspartic acid. The lethal dose of amatoxins for man is assumed to be 0.1 mg/kg body weight and may be contained in a single mushroom [11].

Other cyclopeptides found in *Amanita* mushrooms include heptapeptides referred to as phallotoxins and virotoxins. Phalloidin, the main

component of the phallotoxins, was previously thought to be responsible for symptoms like the gastroenteritis that develops after cyclopeptide mushroom ingestion [15]. However, in beagle dogs, amanitin alone produced the same symptoms as amanitin mixed with phallotoxins rendering unlikely that phallotoxins contribute to human *Amanita* poisoning [16]. Similarly, the virotoxins [17], exhibiting the same toxic activity on the actin cytoskeleton of cells as phallotoxins, are unlikely to play a role in human *Amanita* poisoning.

Phallolysins [18, 19], a group of glycoproteins in amatoxin-containing mushrooms, exert strong hemolytic activity on mammalian red cells, are heat-labile, and break down in the presence of low gastric pH. Hence, they are not believed to contribute to toxicity.

Toxicokinetics of Amatoxins

Pharmacokinetics of Cyclopeptides

Volume of distribution: 0.2 L/kg

Protein binding: none

Mechanism of clearance: renal clearance
83–89%

Metabolism: none

Methods to enhance clearance: Multiple doses of activated charcoal (MDAC) pharmacological blockers of OATP interrupting enterohepatic recirculation

Toxicokinetic data of amatoxins were created in dogs using labeled amatoxins [20]. The volume of distribution is low with 0.2 L/kg body weight. There is no documented metabolism of amatoxin and no protein binding, nor are amatoxins cleaved by proteases. Amatoxins in severe poisonings can be detected in urine up to 4 days whereas detection in blood is only possible for a short time after ingestion [21–24] and may be negative at the patient's admission to the hospital. Amatoxins are rapidly excreted into the urine and bile. A bolus of (^{14}C) Methyl- γ -amanitin given into a beagle dog was excreted up to 85% into the

urine by 6 h [16], rendering extracorporeal purification procedures of blood of little utility. Experiments with perfused rat livers [25] suggested that amatoxins may undergo enterohepatic circulation, and that permanent reabsorption of the toxin by hepatocytes may be crucial for prognosis. This theory was confirmed in experiments with dogs showing that all animals having a bile fistula survived the lethal dosage of 0.1 mg/kg body weight amanitin, while all control animals died [16, 26].

Hepatotoxicity of Amatoxins

Hepatotoxicity of amatoxins is based on the presence of the “Organic Anion Transporting Protein 1B3” (OATP1B3) in sinusoidal membranes of hepatocytes [27]. When the transporting protein was transfected to MDCKII cells, these cells became about 80 times more susceptible to α -amanitin than the native cells, suggesting that OATP1B3 is the transporting protein on hepatocytes most responsible for the import of amatoxins into hepatocytes. The system of the transfected MDCKII cells also allowed for the identification of new competitive inhibitors potentially useful as antidotes in human mushroom poisoning. Moreover, it allowed the analysis of the inhibitory capacities of potential treatments, among them those widely used in the past, like penicillin.

Table 2 shows that silibinin, presently favored as the antidote in Europe with the exception of Italy, is among the most potent inhibitors of

OATP1B3. On the other hand, antamanide proposed by Wieland [10], and penicillin proposed by Floersheim [28] as antidotes, are indeed inhibitors for amanitin transport into cells, although with lower capacity than silibinin.

After the transportation of amatoxins into hepatocytes, the toxins enter the nucleus of the cells and bind to RNA polymerase II (RNAP II) with high affinity (K_D in the nM range). RNAP II is a key enzyme in all mammalian cells transcribing DNA into high nuclear RNA the precursor of messenger RNA, representing the message for all proteins in a cell. It was in 1970 that Meilhac et al. [29], among others, described that this enzyme is inhibited by amanitin. The structure of a complex between amanitin and the catalytic subunit of RNA polymerase II was elucidated by X-ray analysis in 2002 by Bushnell, et al. [30].

As it appears, binding of amanitin blocks the mobility of several enzyme domains involved in the catalytic process, as well as the movement of the enzyme on the DNA strand, resulting in a halt of transcription. Recovery of the enzymatic activity seems unlikely by the very low dissociation rate of the complex, and above all, by the rapid ubiquitinylation [31] of the catalytic subunit, inducing its degradation in the proteasome [32]. A block in transcription of mammalian cells leads to apoptosis *a* programmed cell death.

Clinical Presentation of Amanitin Poisoning: Phalloides Syndrome

Cyclopeptide mushroom poisoning recurs – at last in Middle Europe – from July–October every year. Since collecting mushrooms is a weekend activity, patients tend to seek medical care on Sundays or Mondays. Some people ingest dried or frozen mushrooms and can be poisoned at any time of the year. Signs and symptoms appear between 6 and 24 h after the mushroom meal. Most patients get sick 10–12 h after the meal. The symptoms are severe abdominal pain or cramps, vomiting, and cholera-like diarrhea persisting for the first day. This severe gastrointestinal phase is followed by an apparently

Table 2 Inhibition of OATP1B3-mediated uptake of (³H) *O*-methyl-dehydroxymethyl- α -amanitin in OATP1B3-exposing MDCKII cells [27]

	IC50 (μ M)	(Inhibition capacity (Silibinin = 1.0))
Penicillin G	25	0.02
CCK8	10	0.04
Bromosulphophthalein	3	0.13
Rifampicin	0.8	0.5
Antamanide	0.7	0.6
Silibinin	0.4	1.0
Cyclosporin A	0.3	1.3

improving clinical period of up to 24 h before the hepatic injury progresses to either acute hepatic failure or recovery.

This late onset of symptoms is a distinct and nearly pathognomonic diagnostic feature that, however, may be concealed in three situations. In the first, the amanitin-containing mushrooms were eaten in two meals exhibiting symptoms shortly after the second meal. In the second, the mushroom meal included mushrooms with a short incubation time for gastroenteritis. In the third, the mushroom meal was contaminated by bacteria (*Salmonella*, spp. *Bacillus cereus*) with a delayed onset of symptoms (food poisoning).

In all cases, commencing antidotal treatment should not be postponed even if it turns out not to have been necessary. Last, but not least, even edible mushrooms can produce symptoms with a delayed onset in some individuals. In these cases, however, the symptoms are distinctly milder.

A simplified day-by-day outline describes the course generally seen in fatal amanitin poisoning:

Time Schedule for Amatoxin Poisoning [8]

Day 1	Mushroom meal and symptom-free interval
Day 2	Emesis, abdominal cramps, and diarrhea
Day 3	Liver injury, coagulopathy, mild renal insufficiency
Day 4	Gastrointestinal bleeding, severe coagulopathy if not treated
Day 5	Hepatic encephalopathy Grade II–IV
Day 6	Complete kidney failure
Day 7	Death without liver transplant or human albumin dialysis

This pattern can be influenced by therapy. Thus, the occurrence of an early death due to circulatory failure can be avoided by rigorous fluid replacement. Bleeding can be managed by the administration of fresh frozen plasma or clotting factors. Renal failure, if severe, can be treated by hemodialysis. On the other hand, the onset of acute hepatic failure can be medically managed only for a short period of time.

Of course, not all amanitin poisonings are fatal. Therefore, a classification of severity is essential for deciding on therapeutic measures and prognosis. This cannot be done at admission to the hospital. The best day for a prognosis is the third day postexposure [33].

Severity Grading of Amanitin Poisoning

Grade I:	Patients exhibit gastrointestinal phase with typical delay but do not develop biochemical signs of liver or kidney dysfunction though other persons who have eaten the same meal may develop higher severity grade
Grade II:	Patients show delayed gastroenteritis with a mild rise in transaminases (two- to tenfold upper limit) but no coagulopathy
Grade III:	Patients develop severe hepatic injury, with transaminases > tenfold the upper limit of normal plus coagulopathy manifest by a rise in the international normalized ratio (INR) or a fall of prothrombin index
Grade IV:	Patients are characterized by a steep rise in transaminases and a steep decline in clotting function not improving after day 4, a steep rise in bilirubin and a rise in creatinine after day 3. This phase is usually fatal without liver transplant

It is obvious that Grade I and II patients have the best chances of surviving amanitin poisoning. It can be expected that supportive care with fluid and electrolyte replacement would be sufficient. However, as we cannot fully assess the severity of the poisoning prior to day three, antidotal treatment is indicated up to that time.

Grade III patients are at high risk and should be transferred to a center with the ability for hepatic transplant. Out of a 104 patients from our unit, only 6 could not be classified according to our severity grading: They showed a mild rise in transaminases (<10 times upper limit) but still a decrease in clotting function. All patients survived.

In the effort to differentiate between survivors and patients who need liver transplant, we compared the laboratory parameters of 23 patients who died from amatoxin poisoning with those of

104 patients who survived grade III intoxication [34], equivalent to acute liver injury (ALI) as defined by the US Acute Liver Failure Study Group registry [35].

Transaminases

In our comparison, AST peaked at day three and ALT at day four. AST returned to normal on days 4–6 in survivors. There was no significant difference in transaminases between survivors and fatal cases. Only 69% of the fatal cases had higher transaminases than the survivors. Therefore, the transaminases are not useful for prognosis [34].

Bilirubin

Bilirubin seems to be a rather late indicator for the prognosis. A rise above 5 mg/dl (85 μ mol/l) after day three was associated with a poor prognosis. About 82% of the fatal cases had higher bilirubin than the survivors.

Prothrombin Index

The behavior of the prothrombin index is of high prognostic value. An early and steep drop in prothrombin index (or a rise in INR) is a bad prognostic sign, especially if it does not recover after day 3–4.

There was, however, one interfering factor in our study. To avoid gastrointestinal bleeding, we treated coagulopathy early. Therefore, we saw few prothrombin indices below 20%. Nevertheless, 96% of the fatal cases had a prothrombin index lower than 25%, whereas only 4% of the survivors showed a prothrombin index below 25% [34].

Kidney Function

Severe nephrotoxicity caused by amatoxins has been mostly seen in animal experiments or in kidney perfusion models. In humans, nephrotoxicity is distinctly less than hepatotoxicity [36]. Due to the first-pass effect, the liver takes up in the early stage of the intoxication more of the amatoxins than any other organ. Only a small amount of amatoxins may penetrate into kidney cells as they have no OATP system, even though the major part of the toxins is excreted through this organ. Accordingly, early kidney injury

indicates a poor prognosis. Aside from being a direct nephrotoxin, there are two other mechanisms that can lead to kidney injury. One is prerenal azotemia caused by volume depletion in the early stage of the intoxication. The other is the hepatorenal syndrome in the late stage of the course. Kidney function due to hypovolemia, as indicated by elevated BUN, creatinine, and oliguria, can be normalized by fluid replacement. A slight elevation of serum creatinine on day three and beyond that fails to respond to fluid replacement points to a direct toxic effect on the kidney. Indeed, in our study 93% of the fatal cases had elevated serum creatinine (some very slightly) from day three onward. The combination of prothrombin index (<25%) plus the creatinine value > 106 μ mol/l (1.2 mg/dl) had a sensitivity of 100% for predicting death. All patients who did not meet these parameters survived. The specificity was 98%, as two patients survived with a prothrombin index <25 and creatinine > 106 μ mol/l (1.2 mg/dl).

These criteria are different from the “King’s College Criteria” (KCC) for paracetamol poisoning. In amatoxin poisoning, metabolic acidosis does not ensue before terminal circulatory failure, and this happens (with few exceptions) much later than 24 h. An elevation of serum creatinine portends a bad prognosis at much lower levels than 300 μ mol/l (3.9 mg/dl) as seen by KCC. Grade IV encephalopathy and coagulopathy are the excellent prognostic parameters in both intoxications.

Diagnosis of Cyclopeptide Mushroom Poisoning

History of ingestion of mushrooms known to contain cyclopeptides (*Amanita* spp., *Galerina* spp., *Lepiota* spp.)

History of ingestion of unknown mushrooms with onset of vomiting and diarrhea > 6 h after ingestion

Signs and symptoms of acute hepatic injury 1–3 days after mushroom ingestion

Identification of the mushroom by an expert

Measurements of amatoxins in urine

Identification of spores

The diagnosis procedure is based on three factors:

Identification of the mushroom
Signs and symptoms of the patient
Laboratory findings

Identification

The identification of the relevant mushroom can be made either by direct examination of the mushroom brought in by the patients or by the patient's description. One should bear in mind that the patient might have eaten several different species of mushrooms which might not be in the leftovers. The advice of an expert, a mycologist, or of a staff member in a poison control center should be obtained. This can be done by making a photograph and transmitting it to an expert mycologist or poison control center for a rough first identification. If no offending mushroom is available, a questionnaire can be useful. This should include asking for the shape of the cap (pileus), the stipe, gills, color, and the location where the mushroom was found. Poisonings by toxic *Amanita* spp. can be ruled out if the mushrooms were not taken from a forest from under a tree or a glade. *Amanita* poisoning is not possible if the collected mushrooms had pores and no gills under the pileus. If the patient indicates that they have ingested white-gilled mushrooms that showed a white or pale-green cap, it is highly suspicious that he or she has ingested a poisonous *Amanita* spp.

Clinical Presentation

All patients with signs of severe gastroenteritis occurring more than 6 h after the ingestion must be considered to have amatoxin poisoning until disproven. This clinical presentation is the leading characteristic of this intoxication.

Laboratory Findings

Laboratory tests are less important than are the clinical feature or the identification of the mushrooms. To be effective, treatment must be

commenced long before the diagnosis is verified. Therapeutic measures must never be postponed pending a laboratory result. If the mushroom cannot be identified macroscopically, it is prudent to use leftovers for microscopic search of spores, which will be always successful if parts of the pileus are within the leftovers. *Amanita* spp. have spores that are globose to subglobose, smooth, thin walled, and hyaline positive. They are 7–11 μm long and 6–9 μm wide. In Melzer's solution, the thin walls of the spores turn "amyloid," or blue black. Differentiation from *Agaricus* spores is easy, as *Agaricus* spores are dark brown and do not react with Melzer's solution (30 ml water, 1.5 g potassium chloride, 0.5 g iodine, and 20 g chloral hydrate).

The so-called newspaper test (Meixner's test) is only valuable for the exclusion of amatoxin poisoning if the offending mushroom is available and if the test result is negative. It can be performed in the remains of any part of the mushroom, provided it is unboiled. A piece of the mushroom is firmly pressed on an unprinted margin of a normal newspaper (not a magazine) which contains lignin and the spot is left to dry for 5 min. Then a drop of concentrated hydrochloric acid is placed adjacent to the spot. If the sample contains amatoxins, the overlap area will turn blue. This test is positive in all amatoxin-containing mushrooms. However, it is nonspecific since there are some mushrooms that will test positive but do not contain amatoxins [37, 38].

For detecting amatoxins in biological fluids such as serum, urine, gastric juice, or bile fluid, a sensitive assay is available in some countries. It is an ELISA from Bühlmann Laboratories AG Schönebuch, Switzerland. This test has a high sensitivity and can measure α -amanitin and γ -amanitin (not β -amanitin) in urine down to 1 ng/ml. There is agreement that values above 5 ng/ml in urine are judged as positive. There are other methods which can distinguish between α -amanitin and β -amanitin such as high-performance liquid chromatography and liquid chromatography – mass spectrometry, but they are not generally available. Attempts to determine serum concentrations of amatoxins are not useful as they can be negative by the time of admission to

the hospital. Detection of amatoxins in urine is possible for a longer period but may become negative by 48 h after ingestion. Very early, before symptoms appear, urine amatoxin assays may be negative [21–24]. By the time of hospital admission, amatoxin-poisoned patients may exhibit signs of dehydration, with hemoconcentration, hypokalemia, hyponatremia, hypoglycemia, and elevated BUN but with liver function tests near normal. However, by the second day, severely poisoned patients show a steep rise in transaminases and INR, whereas moderately poisoned patients develop a mild rise in transaminases without coagulopathy.

Treatment

Epidemiology/History

Before the 1980s, treatment of *Amanita* intoxication has followed the belief that the more treatment done, the better. Not to miss the potential benefit of a drug reported to be successfully used in case series, overtreatment by using the combination of many drugs was the rule [7]. Cytochrome C, steroids, vitamin C, and, since the 1960s, thioctic acid [39, 40] were often given in combination and were all believed to exhibit antidotal efficacy.

The mortality rate of amanitin poisoning on average was 30.2% between 1919 and 1958 (87 deaths of 288 cases) [3]. After the introduction of penicillin into therapy by Floersheim [41] in 1971 based on its efficacy in animal experiments [42], mortality fell to 22.4% (46/205) between 1971 and 1980 [43]. However, this improvement may have been due to advances in intensive care medicine. In France, from about 1930 to 1960 a serum antiphallinique [44] was on the market produced by the Pasteur Institute which turned out not to be useful and being a crude horse serum has caused anaphylactic shock [45].

In 1988 Faulstich et al. [46] demonstrated that a monoclonal amatoxin-specific Fab antibody did not neutralize, and even enhanced, hepato- and nephrotoxicity in a mouse model. Enjalbert et al. [47] reviewed retrospectively over a period

Fig. 3 Silibinin (From Wikipedia used under the creative Commons license)

of 20 years up to 2002 the outcome of amatoxin poisonings comparing different therapeutic regimes and concluded that the highest mortality/lowest efficacy was observed in the combination of benzylpenicillin with thioctic acid, with steroids and with any other drug. The only exception was the combination with silibinin. The lowest mortality rate was observed with silibinin (Fig. 3) or *N*-acetylcysteine (NAC) when each of them was used as monotherapy. There is little experience with the use of both of these antidotes simultaneously. Before silibinin was marketed, it was shown that it markedly reduced liver injury in beagle dogs: None of the dogs died when treated with silibinin, whereas 4 of 12 dogs died with signs of hepatic coma at the same dose of amanitin when they were not treated with silibinin [48]. The first experience with silibinin treatment in humans was described by Hruby et al. [49]. Of 18 patients with *Amanita phalloides* intoxication, 17 survived after treatment with a combination of penicillin plus silibinin. The one who died committed suicide by mushroom ingestion. In Portugal, the mortality rate between 1990 and 2008, without mentioning the kind of treatment, was 11.8% [50, 51]. According to the annual report of the American Association of Poison Control Centers [52] 2012, 4/44 (9%) patients died in the US in 2012. In Switzerland between 1995 and 2009, 5 of 32 (16%) patients died [53].

It may be that there are big differences in the toxicity of amanitin-containing mushrooms even in the same species from country to country. The Italians had the best results even with benzylpenicillin treatment alone. In a monocenter study (Florence) [54], they had only 2 deaths in 105 patients between 1988 and 2002 and 10 deaths

out of 242 patients (4.1%) on NAC treatment in Pavia between 2002 and 2012 [55]. In 11 patients treated with NAC in combination with benzylpenicillin all survived, one with liver transplant [56]. The worst results occurred in Australia where out of 12 patients, 9 of them having received silibinin 4 died (33%) [57].

These data are confusing. A multicenter prospective randomized study comparing different regimes as such as *N*-acetylcysteine versus silibinin cannot be done because it would likely require approximately 600 patients in each arm. A comparison of supportive treatment alone to silibinin or NAC cannot be undertaken for ethical reasons as empirical data indicate efficacy of silibinin, benzylpenicillin, and NAC.

A retrospective study published in 2008 [58] analyzed for the best antidotal treatment. After silibinin became available in 1980, penicillin treatment was still accepted so that a combination of silibinin + penicillin became the therapy of choice. Later, after realizing that silibinin and penicillin were both active in blocking the OATP, silibinin monotherapy was established. Included in the study were 614 patients, of which 388 had enough data for the evaluation. The patients came from the Toxicological department in Munich, from post marketing surveillance by the Madaus firm, and from Vienna, Mainz, Berlin, and Schweinfurt. 248 patients were treated with penicillin plus silibinin, 118 patients had a silibinin monotherapy. In the group that received the combination therapy, 8.8% died or had liver transplantation (21/1). In the group treated with silibinin only, 5.1% of the patients died or had liver transplantation (1/5). Though the risk of death in the silibinin mono-group was reduced by 40% the difference was statistically not significant. A longer period before the appearance of symptoms after the mushroom meal was associated with significant reduction of the risk of death (odds ratio, 6.17: 95% CI, 1.77–21.3; $p < 0.004$, <12 h: >12 h). A later start of silibinin therapy > 24 h versus < 24 h was associated with an increased frequency of death (OR, 3.0: 95% CI, 0.96–9.29; $p < 0.059$). This was true even though the patients with a shorter latency period exhibited

higher severity grades. From this study we concluded that early monotherapy with silibinin is efficacious. (Grade II-2 evidence) The ambiguity in all of these studies is that the distribution of patients with different severities in the different groups cannot be judged at admission and the influence of treatment before severity is assessed is not known. Nevertheless, the reduction of the mortality rate from over 30–20% with penicillin to 5–8% with silibinin argues for the efficacy of silibinin. In a highly sophisticated multidimensional multivariate statistical analysis using different logic including the data of Enjalbert [47], silibinin and NAC were found to be effective [59]. These statistics, however, including the majority of cases treated with silibinin in combination or alone comes from the firm producing silibinin [60]. The mortality rate was 7% (107 fatal cases of a total of 1491 cases).

Indications for ICU Admission in Cyclopeptide Mushroom Poisoning

Suspected cyclopeptide mushroom ingestion (gastroenteritis > 6 h) and elevated transaminases from day two- on $>$ tenfold upper limit

Severe dehydration and loss of electrolyte on the day one with increased hematocrit and/or BUN, and/or hypoglycemia, and/or hypokalemia and/or hyponatremia

Treatment of Cyclopeptide Mushroom Ingestion

Fluid and electrolyte resuscitation

Glucose solution for hypoglycemia and nutrition

Enhanced diuresis to keep up kidney function for elimination of amatoxins

Multiple doses of activated charcoal to reduce enterohepatic recirculation

Antidotal treatment with silibinin possibly in combination with NAC but not in combination with penicillin

Antidotal treatment with high-dose penicillin if silibinin is not rapidly available, possibly in combination with NAC

(continued)

If started on penicillin, switch to silibinin as soon as silibinin is available

Liver transplantation if necessary

Bridging with human albumin dialysis (MARS[®]) if patient is in coma until donor liver is available

Vitamin K + clotting factors + FFP if INR is > 6

Hemodialysis for renal failure

Treatment in Detail

Treatment of Dehydration

During the first 24 h after admission, volume replacement of 4–6 l is usually necessary. Fluid replacement must occur intravenously because of persistent vomiting and diarrhea. We recommend glucose (5–10%) with sodium and potassium (200–300 meq/24 h each) added. Because of volume depletion, fluid status and urine output should be monitored closely and serum potassium and sodium assayed and corrected as needed. As a rule, this approach will achieve initial stabilization. Clinically, the endpoints of fluid resuscitation are resolution of hypotension, normalization of the hematocrit and BUN, and increase in the central venous pressure. If hypoglycemia and hypotension persist, this may indicate inadequate resuscitation, early liver failure, or shock due to sepsis caused by the necrotic liver. Because in the Italian experience [54, 55, 61], forced diuresis was associated with good survival rate resuscitation to a brisk urine output is recommended by the authors (Grade III recommendation) as there is no doubt that maintaining glomerular filtration is important for the excretion of amatoxins. However, it is not clear if forced diuresis supported by loop diuretics such as furosemide enhances amatoxin clearance. Caution should be exercised, however, in cases of kidney failure due to the nephrotoxic effect of the amatoxins, in which fluid overload may occur and lead to cerebral edema, especially in combination with impending hepatic encephalopathy.

Removal of Toxin

The ability to do successful decontamination is strongly dependent on the time of admission to hospital. Only a small percentage of patients – two cases in our collective experience – arrived at the hospital during the early asymptomatic phase. One suicidal person and one patient with doubts about the ingested mushrooms sought help during this phase (<8 h). In these very rare cases, primary decontamination in the form of a high-dose activated charcoal and secondary decontamination with hemoperfusion is recommended by us. Activated charcoal should always, in our opinion, be given for primary and secondary decontamination. Charcoal binds amatoxins left in the intestine and interrupts enterohepatic circulation of the toxins. Our recommended dose is 50 g as a start and 12.5 g/h during the next 3 days. In some cases, a stomach tube may be necessary through which charcoal is continuously dispensed. If not using forced diuresis as discussed above, sufficient diuresis after volume replacement should be maintained. We recommended a rate volume replacement of 200 ml/h for 2–3 days [62].

In the 1980s, hemoperfusion was extensively used with the aim of removing amatoxins from the blood. Looking into more detail of the toxicokinetics, it became obvious that there is no toxin to be removed at that time when this therapeutic procedure can usually be started [23, 61, 63]. In 22 cases of amanitin poisoning in which we measured amatoxin levels in blood at admission, only three patients had measurable amatoxins, between 2 and 4 ng/ml. The amount of toxin removed by hemoperfusion in these patients was small. Hemoperfusion, hemodialysis, plasmapheresis, or human albumin dialysis are not, therefore, useful for secondary detoxification. One exception to that rule might be the very early presentation as seen in the suicidal patient who had taken a lethal dose of *Amanita phalloides* (five mushrooms) and survived when hemoperfusion was started before symptom onset [8].

As amatoxins are readily excreted through bile fluid, it might be reasonable to interrupt the

enterohepatic circulation of the toxins completely by suction of the duodenal fluid or even by inserting a nasobiliary tube into the ductus choledochus through the papilla Vateri and draining the whole bile fluid from the body. This was performed in a few cases [64] (Todd Mitchell personal communication). There may be some risk in this procedure, such as pancreatitis or bleeding from the papilla Vateri. A final conclusion about the efficacy of this procedure cannot yet be drawn. The most benefit may be from activated charcoal administration such that charcoal is present in the duodenum.

Antidotal Treatments

Benzylpenicillin, silibinin, and NAC are presently used as antidotes. Animal models and experiments in hepatocyte cell cultures [27] show that the uptake via OATP 1B3 is inhibited by many substances. This holds true both for penicillin and silibinin, but silibinin at the recommended dose is 50 times more potent than penicillin (see Table 2) in inhibiting amanitin uptake into the liver cell. The mechanism by which NAC may act is not clear. It is likely to be a combination of scavenging the toxin, antioxidant action, and reactivation of glutathione, as in paracetamol poisoning. There are no known adverse effects of silibinin at the dose blocking the transport system for the amatoxin uptake into the liver. In contrast, penicillin in effective doses may induce convulsions, especially if cerebral edema is imminent. In addition, penicillin may cause anaphylactic shock, interfere with coagulation, and induce pseudomembranous enterocolitis.

Due to these risks and the better results achieved with silibinin monotherapy, we recommend that penicillin should only be used if no, or until, silibinin is available. This might be a problem for the treatment outside of Europe where silibinin is not approved and therefore may not be readily available. In the US, silibinin is available as an investigational drug. A combination of penicillin as well as silibinin with NAC might be wise as NAC certainly has an antioxidative effect and can help to restore glutathione which is depleted in *Amanita* poisoning.

For dosing silibinin, we suggest – contrary to the instruction leaflet – a continuous infusion after a bolus. The bolus is sufficient to create therapeutic silibinin levels within one hour which might be of importance as many patients come in late. The bolus is 5 mg/kg body weight within one hour followed by 20 mg/kg body weight in a continuous infusion over the next 24 h. This dose is equivalent to the dose in the instruction leaflet, where administration in intervals is advised. There is no limit for the period of silibinin administration. In patients that can be classified as severity grade I–II (mild and moderate), the infusion can be terminated on day three. We recommend that all other patients should receive silibinin infusion until day six or until transaminase levels and INR are declining significantly. Silibinin treatment should also be used during the asymptomatic period in the few cases that present early after a suspicious mushroom meal. If no symptoms develop within 24 h, silibinin treatment can be terminated. It is essential that silibinin treatment be commenced in all cases in which amanitin poisoning is suspected.

The suggested dose for penicillin is 1,000,000 U/kg body weight on the first day and 500,000 U/kg body weight on day two and three. After the third day, penicillin treatment is no longer advised if the patient is progressing toward hepatic encephalopathy. From the abovementioned study comparing penicillin plus silibinin in combination to silibinin monotherapy, combination therapy seems not to be advantageous. Since both penicillin and silibinin are competitive inhibitors of the amanitin transporting system, they may interfere negatively with one another. Therefore our advice is to use silibinin alone if it is available.

In a mouse model, no change in survival or hepatic enzyme elevation was seen comparing amanitin poisoned mice given NAC treatment compared to control animals [65]. *N*-acetylcysteine has been used successfully, especially in Italy [55, 56].

The specific NAC protocol used in Italy is not exactly the same of that used in paracetamol poisoning. The differences are related to both NAC loading dose and duration of treatment (total

dose). They administer an intravenous loading dose of 150 mg/kg in no less than 90 min (to minimize the adverse effect anaphylactoid reaction), followed by the maintenance dose of 300 mg/kg/24 h (this is the so-called Pavia amatoxin protocol). This regimen of continuous infusion is started at Emergency Department admission in patients with suspected *Amanita* poisoning, and then:

- Is stopped if the urinary levels of alpha-amanitin are negative.
- Is continued if the urinary levels of alpha-amanitin are positive. The intravenous regimen of continuous infusion of 300 mg/Kg/24 h is subsequently.
 - Stopped 48–72 h in patients that don't develop hepatitis and with negativization of urinary alpha-amanitin levels.
 - Continued as long as the alpha-amanitin levels remain positive (even in the absence of hepatic damage) or as long as ALT decrease below 200 UI/L in patients that developed hepatic damage. In the Italian experience (Carlo Locatelli personal communication) in this last group of patients, the continuous infusion regimen of 300 mg/kg/die was continued for an average of 7 days (minimum 3 and maximum 21 days).

No adverse effects have been published from using NAC in this context, although anaphylactoid reactions can be expected with intravenous administration. Other substances such as steroids, vitamin C, cytochrome C, and thiocetic acid are no longer recommended. These interventions have not shown any additional benefit when combined with silibinin, penicillin, or NAC [47, 60]. In mouse/rat models picrothiza and cimetidine [66–68] showed some protective effects. Other non-penicillin antibiotics, like cephalosporins, were used instead of benzylpenicillin [69, 70], but there are too few cases to assess their efficacy. In cell culture experiments, all antibiotics used (benzylpenicillin, ceftazidime, and rifamycin) exhibited the same effect in inhibiting alpha-amanitin uptake into liver cells [71].

Hyperbaric oxygen therapy (HBO) has also been investigated in amanitin poisoning and seems to be useless. In a mouse model, HBO compared to normobaric condition did not exhibit better outcome after a toxic dose of amanitin [72].

Coagulopathy/Prevention of Bleeding

Coagulopathy in amanitin poisoning is due to a lack of hepatic synthesis of clotting factors. This is a sign of liver dysfunction. In amanitin poisoning, complications of gastrointestinal or intracerebral hemorrhage are typically seen from day three onward in grade III (severe ALI) intoxication. Absorption of blood from the intestine promotes hepatic encephalopathy due to ammonia production from blood proteins. Gastric hemorrhage was common in *Amanita* poisoning prior to modern therapy with proton pump inhibitors (PPIs). Because of this patients whose prothrombin index fell below 25% were treated with clotting factors or FFP. Further, these patients receive low dose of heparin and AT III in order to avoid DIC [73]. Since the introduction of PPIs, gastric bleeding has mostly disappeared in patients with *Amanita* poisoning. In most studies among all criteria for liver transplant (LTx) a prothrombin index below 10% was the best prognostic value for a lethal outcome [74, 75]. If the prothrombin index stays below 10%, or the INR is above 6 from day 3–4, we recommend the administration of clotting factors and LTx is indicated. We further recommend that vitamin K be given intravenously as soon as there are signs of a coagulopathy to allow resynthesis of clotting factors. (Grade III recommendation) PPIs such as omeprazole or pantoprazole appear to help to avoid gastric bleeding and we recommend that they be routinely administered.

Grades of Hepatic Encephalopathy

Prevention and Treatment of Hepatic Encephalopathy

There are four grades of hepatic encephalopathy (Table 3) based on intellectual functions (such as concentration), sense of time, memory, and the ability to calculate. Behavioral abnormalities like

Table 3 Grades of hepatic encephalopathy

Grade	
0	Normal level of consciousness but abnormal liver function
I	Sleeping disturbance, lack in concentration, slow reaction time, excitable, mood swings, disturbed motor skills, asterixis, degradation of writing
II	Lethargy, no sense for time, dyscalculia, muscle reflexes reduced, slurred speech
III	Disorientation, confusion, cloudy, loss of memory, aggression, delusion, muscle reflexes increased, nystagmus
IV	Coma, no reaction to pain, opisthotonus, mydriasis barely reacting to light

rapid mood changes, anxiety, aggression and paranoid thinking may also be present. Neuro-muscular disturbances manifest by hyperreflexia, may occur. As encephalopathy progresses, hand-writing capacity deteriorates, which can be monitored by a daily writing test. Asterixis, disturbed speech, and increased muscle tone are characteristic. In the final stage, the patient becomes comatose. The electroencephalogram (EEG) usually shows slow waves before the clinical manifestation of coma, and therefore we recommend EEG monitoring in grade III patients [76]. If the patient is in coma, intracranial pressure (ICP) should be measured either continuously by an implanted transducer once coagulopathy has been corrected or by Doppler noninvasive monitoring [77]. If irreversible brain damage has already ensued, LTx is not indicated. Glucose infusion, if necessary in combination with insulin, is the appropriate basic parenteral nutrient because it can prevent hypoglycemia and may be required for the regeneration of hepatocytes. Further, parenteral nutrition should contain branched-chain amino acids as they may help to prevent encephalopathy. 400 mg of rifaximin, given orally twice a day, will reduce the bacterial population of the colon and thus prevent the invasion of enterotoxins into the portal system. Lactulose decreases the bacterial ammonia production in the intestine leading to less absorption of ammonia and thus helps to prevent hepatic encephalopathy. The dosage is 10 g, four times a day.

Table 4 Criteria for liver transplantation

<i>King's College criteria for non-paracetamol poisoning</i>	
INR	> 6.5 on its own or
Serum bilirubin	> 300 μmol/l and
Jaundice to coma	>7 days and
Drug or infection in history	
<i>Clichy criteria</i>	
Encephalopathy grade	III to IV
Factor V	< 20% age < 30
Factor V	<30 age > 30
<i>Clichy (Escudé) criteria for Amanita phalloides</i>	
Ingestion to symptoms	< 8 h
Prothrombin index	< 10% ~ INR > 6
<i>Munich (Ganzert) criteria</i>	
Prothrombin index	< 25% under treatment with clotting factors from day 3 onward and
Creatinine	> 106 μmol/l from day 3 onward

Liver Transplant: Bridging Systems

If hepatic encephalopathy has developed to such a degree that the patient is not arousable and not reactive to painful stimuli (stage IV), liver transplant is inevitable. However, by then, it may be too late to organize LTx even on high urgency as intracranial pressure may lead to irreversible anoxic injury or brain death within a very short time. In contrast, patients have recovered from stage III encephalopathy [74] without transplantation. We recommend treating stage III or IV encephalopathic patients with a human albumin dialysis using the MARS® [78, 79] or by a fractionated plasma-separation system using PROMETHEUS® [80] (Grade II-3 recommendation). With these methods it may be possible to remove endogenous toxins which accumulate during liver failure, to lower intracerebral pressure, and to improve the circulatory insufficiency [81–83]. It should be stressed that these methods do not remove amatoxins, which do not bind to albumin and, as reviewed above, clear from the blood in the very early stages of intoxication. Various criteria have been used to decide on liver transplant before coma ensues. All criteria (see Table 4 criteria for liver transplant) have one sign in common: If the prothrombin index is below 10% or

the INR above 6, when not treated with coagulation factors or FFP, the sensitivity for fatal outcome is 100%. The specificity never reaches 100% because there are some cases that recover despite severe coagulopathy. Specificity reaches 100% if the severely impaired coagulation function persists. The KCC for paracetamol do not apply to amanitin poisoning because in amanitin poisoning kidney failure and metabolic acidosis are rarely seen early. KCC for non-paracetamol poisoning also do not fit because the time between jaundice and coma is never > 7 days in amatoxin poisoning. By this time the patient has either survived or is dead. The Clichy criteria do not apply because there are not enough data on the measurement of factor V and because encephalopathy grade III patients have survived in amanitin poisoning. The criteria of Escudie [74] do not fit because we have had patients who died with a longer asymptomatic period than 8 h. The Munich [34] criteria were developed especially for amanitin poisoning. (Table 4). Included in this study was the largest number of fatal amanitin poisonings compared to severe but survived poisonings. The combination of clotting function (prothrombin index <25% under clotting factors substitution) and impaired kidney function gave the best prognostic factor. The Munich and Clichy criteria were criticized by Ferreira [75]. But in their cases, liver transplant was done before encephalopathy or kidney insufficiency were reached, so the question remains as to what would have happened without liver transplant (post hoc fallacy).

The decision to pursue transplant is not to be made easily. Liver transplant is a major surgical intervention with attendant risks and requires a lifetime of immunosuppression. One should be as sure as possible that the patient would not likely survive without LTx, particularly because, as a rule, no long-term hepatic damage is expected. There is only one publication [84] that states chronic histopathological changes in liver biopsies 6 months after the intoxication. Other follow-up studies show complete recovery with the exception that kidney failure can persist in a few cases [85].

Special Situation Demanding Early LTx

About 10% [58, 74] of patients with *Amanita* poisoning die early in the course of disease. This is due to multiorgan failure with refractory shock. The reason is most likely a necrotic liver with endotoxins leaking into the circulation. Signs and symptoms of this condition include hypotension not responding to vasopressors, metabolic acidosis, and hyperdynamic circulatory failure with reduced peripheral resistance. Though not described specifically for amanitin poisoning, the only way to possibly save these patients is total hepatectomy followed by bridging using MARS[®] or PROMETHEUS[®] and liver transplantation as soon as an organ is available. This procedure was successful in patients with other causes of fulminant liver failure [86].

Auxiliary Partial Liver Transplantation

Single cases have been described in which partial orthotopic liver transplantation from a living donor for hepatic failure was performed [87]. To our knowledge this has never been done in amanitin poisoning. This procedure would allow the damaged liver to recover, and by weaning the immunosuppression after the recovery of their own liver, the graft will be rejected and disappear. This method seems to be best suited for children as their liver regeneration is best [88].

It may be reasonable to infuse silibinin during the perioperative period to avoid amanitin-induced damage to the new liver by redistribution of amatoxins from the explanted liver or kidney. This was described in two cases [89] in which the transplanted liver was injured and postmortem pathological examination of the implanted liver showed a similar histological picture as the patient's earlier explanted liver. This consideration was the reason that silibinin perioperatively is used in all cases transplanted in our center in Munich [90].

Successful liver transplantation in amanitin poisoning has been reported worldwide since 1985. The first liver transplantation in amanitin poisoning was performed in a child by Woodle [91]. This was followed by many more reports of

effective transplants [15, 90–94]. The survival rate of the graft and the patients is better than for other indications for hepatic transplant as in amanitin poisoned patients, other underlying diseases are absent.

Sequelae

Though histopathological changes in liver biopsies have been reported 6 months after surviving an amanitin poisoning [84], we have never seen this progress to chronic liver disease or cirrhosis. Several patients have come back to see us after years. Their liver function showed no impairment. But as there are no systematic investigations into this question, more follow-up studies might be needed. At discharge, of our patients some had slightly elevated ALT and bilirubin which later normalized.

Two cases are described in the literature [95–97] with severe bowel dysfunction after recovery from amanitin poisoning. The first case developed intractable diarrhea and dilatation of the colon requiring decompression by a catheter. The second case developed severe abdominal pain and diarrhea with pain and diarrhea for several weeks, after survival of the amatoxin poisoning. The histology revealed ulcerating ileocolitis. Follow-up histology after six months was normal [96].

In a few cases of survival of severe amatoxin poisoning, permanent kidney failure persists. An elderly patient permanently required hemodialysis and a second one had a renal transplant 4 years after liver transplantation [98].

Special Population

Immigrants

At least in Germany, it has become obvious that immigrants from Eastern Europe and the Middle East are at risk because of their tendency to forage for mushrooms and the likelihood of misidentifying a poisonous one [99]. As recently as 2015, a family of refugees from Syria was so poisoned [100]. The

reason this population is at risks is that they might not be aware of the danger of mushroom foraging or they may collect amatoxin-containing mushrooms that are similar to edible mushrooms in their home country. The same may come true for US people if their ancestry is from Germany, France, Italy, Russia, or Poland, as these countries have a fungophile tradition.

Pediatric Patients

Children are at greater risk than adults of experiencing fatal hepatic injury. While this is a terrible tragedy, it happens frequently. In these cases, parents may survive their intoxication, while their die. The mortality rate in small children was 50% [3, 53], before liver transplantation was available [3, 53]. There are many calls to Poison Control Centers when parents discover that their small children have eaten mushrooms while playing unattended outside in grassland or during a walk in a forest. In these cases, a rapid identification of the mushroom by an expert is required to both avoid overtreatment and to start antidotal treatment immediately if the suspicion of an amanitin-containing mushroom being ingested is high. Fortunately, in these cases the amount of mushroom eaten is usually not large.

Pregnant Patients

There are a number of case reports where pregnant women were poisoned by amanitin-containing mushrooms. In these cases, the toxic ingestion happened in the second trimester of pregnancy at the 22nd, 23rd, and 28th week [101–104] with no damage to the fetus. Even cases of first-trimester ingestion at the 11th week of gestation the birth and the development of the infant proceeded without incident [105]. Obviously the toxins of the mushrooms do not cross the placental barrier [105]. Therapeutic abortion might become necessary if the life of the mother is at jeopardy in early pregnancy [106]. In a retrospective review of 22 cases of pregnant women poisoned by amatoxin-containing mushrooms, the mean birth weight was lower than in controls. Two malformations, one due to alcohol abuse of the mother, were observed [107]. Abortion is

generally not indicated as normal fetal development would be expected, except in extreme cases.

Other Special Population

In collective review of *Amanita* poisonings [34, 58], a higher mortality rate was not seen in the elderly.

The Future

Polymyxin B in an in silico study turned out to protect RNAP II or even might free the polymerase from amanitin docked to it. In a mouse model, polymyxin B significantly decreased the amatoxin-induced hepatic and renal injury. When polymyxin B was administered 4,8,12 h post-alpha-amanitin exposure, 50% of the animals survived whereas in the control group, 100% died [108]. Future clinical studies will determine if this is an efficacious antidote.

Criteria for ICU Discharge in Cyclopeptide Mushroom Poisoning

Resolution of coagulopathy

Resolution of hepatic transaminases (not bilirubin, which may persist for longer)

Resolution of renal function

Common Errors in Cyclopeptide Mushroom Poisoning

Taking the symptoms for food poisoning or other origin not asking for mushroom consumption

Discounting the possibility of amatoxin poisoning because the ingestion of *Amanita phalloides*, *Amanita verna*, or *Amanita virosa* was excluded (other mushroom contain amatoxins like *Galerina* spp. and *Lepiota* spp.)

Discounting the possibility of amatoxin poisoning because the symptoms appeared

“too soon” (other mushrooms with short asymptomatic period coingested)

Discharging the patients after initial resolution of gastrointestinal symptoms (even if the patients want to be discharged)

Waiting for laboratory results and not starting antidotal treatment

Waiting too long to transfer the patient to a liver transplant center

Key Points in Cyclopeptide Mushroom Poisoning

Keep cyclopeptide mushroom poisoning in the differential diagnosis for a patient with gastrointestinal complaints, and ask all patients with gastroenteritis if they have consumed mushrooms.

Contact regional poison center for help in diagnosing and treating suspected cyclopeptide mushroom ingestion as they know where the antidote can be received from and where the mycologist experts are.

Provide initial and continuing treatment of fluid and electrolyte abnormalities, treat coagulopathy, and encephalopathy later on.

Treat as early as possible with available antidotes.

Make early contact with regional liver transplant center and consider early transfer to a transplant center.

Report cyclopeptide mushroom ingestion cases to local regional surveillance centers (in the US). Give warnings to the press.

To Be or Not to Be Depends on Early Therapy

A mushroom meal the eaters hits

Delayed by belly cramps and shifts

Please treat as promptly as you can

To be that woman or that man

That saves the mushroom eater's life

And all his children and his wife

The mushroom species *Gyromitra* (formerly *Helvella*) *esculenta* grows throughout the northern hemisphere including North America, Europe, and Asia. It is commonly found in coniferous and hardwood forests. The species fruits in early spring (later at higher elevations), often where snow has recently melted. *G. esculenta* is a member of the fungus class Ascomycetes, meaning that it has no gills, tubes, or spines but develops its spores in saclike structures called *asci*. The mushrooms are moderately sized measuring 3–10 cm across, are brown to reddish brown, and have wrinkled caps, with a brainlike or saddle shape (Fig. 1). The stalk is white to brown in color, thick, and hollow, usually with a single chamber.

G. esculenta may be misidentified as Morchellaceae due to similar appearance. Morchellaceae (genera *Disciotis*, *Morchella*, and *Verpa*), or “true morels,” are highly sought for consumption yet capable of causing significant

gastrointestinal (GI) distress and neurological illness if consumed raw [1, 2]. *G. esculenta*, or “false morel,” contains gyromitrin, which is metabolized to the toxic monomethylhydrazine (MMH) (Fig. 2). Other mushrooms that contain gyromitrin are listed in Tables 1 and 2 [2–7].

Over 6,500 mushroom exposures were reported to the American Association of Poison Centers in 2013; 29 of these involved gyromitrin-containing species with no deaths [8]. *G. esculenta* was second only to *Amanita* spp. for mushroom-induced deaths during the first 72 years of the twentieth century [9]. A European review of 513 cases of gyromitrin toxicity reported a 14% mortality rate [10]. Despite its toxicity, *G. esculenta* has been sold for consumption, canned and raw, in some European markets.

Poisoning can occur after the ingestion of either raw or cooked *Gyromitra* mushrooms; however, their toxins are volatile and cooking decreases the toxicity. The boiling point of gyromitrin is 64 °C (147.2 °F) and of MMH is 87 °C (188.6 °F). Parboiling (repeated boiling with water exchanges) is utilized to prepare *G. esculenta* for consumption, though its efficacy for removing toxicity is not well established. Gyromitrin can be detected in dried, boiled, and lyophilized specimens [11, 12]. Several specific gyromitrin homologues have been identified in the steam during boiling. Toxicity from inhaling the steam or drinking the cooking water has been reported [11]. Drying the mushrooms in outdoor air at 20 °C (68 °F) over 14 days removed 98.9% of an intermediate metabolite, *N*-methyl-*N*-formylhydrazine (MFH) (see Fig. 2), and boiling 100 g of *G. esculenta* in 300 mL of water, pH of 7.8, for 10 min removed 81.3% of the toxin. Parboiling and acidifying the water promote removal of toxin [11].

Fig. 1 *Gyromitra esculenta*, which contains the hepatotoxin gyromitrin (From Phillips R: *Mushrooms of North America*. Boston, Little Brown, 1991, with permission)

Biochemistry and Clinical Pharmacology of *Gyromitra* Toxins

In the nineteenth century, Bohm and Kulz [13] falsely identified helvellic acid as the compound responsible for the toxicity of *G. esculenta*. List and Luft [14] were the first to identify gyromitrin correctly (acetaldehyde MFH) in 1967 with subsequent structural confirmation via direct synthesis.

Fig. 2 Metabolism of gyromitrin

Table 1 Mushrooms known to contain gyromitrin^a

Scientific names	Common names
<i>Gyromitra ambigua</i> and <i>Gyromitra infula</i>	Hooded false morel
<i>Gyromitra esculenta</i>	False morel, beefsteak (brain) mushroom, elephant ears, turban fungus, lorchel

^aThere is low consensus among experts in terms of nomenclature and classification of these mushrooms [2–7]. A further discussion of the classification of mushrooms is provided in ► Chap. 107, “Overview of Mushroom Poisoning”

Under physiologic conditions, gyromitrin is metabolized rapidly to acetaldehyde and MFH (see Fig. 2). This reaction has been reproduced experimentally under conditions mimicking the gastric environment [15]. Subsequently, MFH is slowly hydrolyzed to MMH and formic acid. Metabolism of MFH by the hepatic mixed-function oxidase system has been studied and may explain gyromitrin’s hepatotoxic effects [16]. At this time, at least 11 structurally similar hydrazones (hydrazine homologues) have been identified in *G. esculenta* [11, 17].

Pathophysiology of Toxic Effects

Effect on Pyridoxine Metabolism

Gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the central nervous system (CNS), is synthesized from the excitatory

Table 2 Mushrooms thought to contain gyromitrin^a

Scientific names	Common names
<i>Cudonia circinans</i>	
<i>Cyathipodia macropus</i>	
<i>Gyromitra brunnea</i> or <i>Gyromitra fastigiata</i>	Brown false morel
<i>Gyromitra californica</i>	California false morel, umbrella false morel
<i>Gyromitra caroliniana</i>	Carolina false morel, big red mushroom
<i>Gyromitra gigas</i> (including <i>Gyromitra montana</i>)	Giant false morel, snow (snowbank) false morel
<i>Gyromitra korfii</i>	Bullnose
<i>Gyromitra sphaerospora</i>	Round-spored gyromitra
<i>Helvella crispa</i>	Common white helvella
<i>Helvella lacunosa</i>	Black helvella
<i>Leoptopodia elastica</i>	
<i>Leotia lubrica</i>	Slippery cap
<i>Neobulgaria pura</i>	Beech jelly-drop cup
<i>Otidea onotica</i>	Lemon-peel cup
<i>Sarcophaere crassa</i>	Violet star cup
<i>Spathularia flavida</i>	

^aThere is low consensus among experts in terms of nomenclature and classification of these mushrooms [2–7]. A further discussion of the classification of mushrooms is provided in ► Chap. 107, “Overview of Mushroom Poisoning”

neurotransmitter glutamate by the enzyme glutamic acid decarboxylase. This reaction requires pyridoxal phosphate, the activated form of pyridoxine (vitamin B₆), as a cofactor (Fig. 3). MMH inhibits glutamic acid decarboxylase, causing

Fig. 3 Inhibition of γ -aminobutyric acid synthesis by monomethylhydrazine

increased concentrations of glutamate and decreased concentrations of GABA. MMH also blocks the phosphorylation of pyridoxine by inhibiting pyridoxine phosphokinase. In addition, MMH binds and inactivates phosphorylated pyridoxine, inhibiting its role in other various reactions [18]. These effects on GABA synthesis account for the CNS excitation (e.g., seizures) seen with poisoning by gyromitrin-containing mushrooms.

Fast Versus Slow Acetylators and Difference in Toxicity

The ability to acetylate xenobiotics via hepatic metabolism varies within the human population and is genetically determined [19, 20]. There is a dichotomous distribution of acetylator phenotypes in humans, and people can be labeled as *slow* and *rapid* acetylators. After ingestion of *G. esculenta*, hydrazine compounds may be acetylated, which seems to protect against neurologic effects but to enhance hepatotoxicity. Formation of acetylhydrazine, the first step in the biotransformation of hydrazines, promotes formation of hepatotoxic alkylating radicals [20–24].

Oxidative Stress

Gyromitrin toxicity produces oxidative stress that overwhelms endogenous antioxidant systems that normally maintain methemoglobin (MetHb) concentrations of less than 3%. MetHb is formed by oxidation of hemoglobin's iron, converting it from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. MetHb is incapable of carrying oxygen and shifts the oxygen dissociation curve to the left, hindering oxygen delivery, thereby producing cyanosis and tissue hypoxia. Methemoglobinemia is discussed in detail in ► Chap. 30, "Toxicant-Induced Hematologic Syndromes."

Inhibition of Diamine Oxidase

Diamine oxidase (histaminase) is a regulatory enzyme responsible for the metabolism of histamine. It is found in rapidly proliferating tissues, such as intestinal mucosa and bone marrow. MFH noncompetitively inhibits diamine oxidase *in vitro* [25]. Inhibition of diamine oxidase can produce histamine concentrations that cause flushing, abdominal pain, nausea, vomiting, diarrhea, and headache. These clinical findings are similar to scombroid poisoning.

Mixed-Function Oxidase Inhibition

During the oxidation of gyromitrin and MFH, highly reactive nitrosamide intermediates are formed that are capable of decreasing hepatic cytochrome P-450 concentrations in rat models [16]. These nitrosamide metabolites may account for some inhibition of the mixed-function oxidase system and hepatotoxicity.

Inhibition of Folate Conversion to Folinic Acid

Folate is the inactive form of a B-complex vitamin essential for protein synthesis and erythropoiesis. Dihydrofolate reductase (Fig. 4), the enzyme that converts folate to folinic acid (the active form), is inhibited by the hydrazones in *G. esculenta*. Folinic acid (leucovorin) administration may maintain normal cellular catabolism.

Carcinogenicity and Embryotoxicity

There have been significant increases in neoplasm development reported in animals fed fresh *G. esculenta* or its prepared hydrazones [26–40]. MMH causes teratogenic effects in toad embryos [41] and has shown a dose-dependent decrease in pregnancy rates of exposed rats [42]. There is insufficient data to predict possible carcinogenic and mutagenic effects in humans.

Fig. 4 Inhibition of tetrahydrofolate synthesis by hydrazones from *Gyromitra esculenta*

Clinical Presentation and Life-Threatening Complications

Interpersonal Differences in Dose Response: The Individual Threshold Dose

Individual responses to *G. esculenta* are varied and range from no effect to severe poisoning and death. Dose-dependent and interpersonal differences in response determine the minimal amount of ingested mushroom necessary to cause toxicity in any given patient. This phenomenon is known as the *individual threshold dose* [2, 43, 44]. Patient factors, such as age, size, health, and metabolic capability (i.e., slow versus fast acetylators); amount ingested; preparation technique; and amount of co-ingested food may affect the clinical course. Some report a kindling or sensitizing effect, where toxicity only occurs after repeated exposure. Others suggest that bioaccumulation of gyromitrin may lead to poisoning [21]. It has been observed that a person may eat *G. esculenta* for years but develop poisoning only after consuming a large, threshold amount.

There also is considerable variation in the potential of any gyromitrin-containing mushroom to cause toxicity. The toxicity of an individual mushroom is determined by several factors, including genetic strain, hybridization, environmental conditions (soil, temperature, light), age, and internal distribution of toxin. The altitude at which the mushrooms grow has been identified as a strong determinant of toxin content. Mushrooms grown at mid-range altitudes often contain five times more MMH than samples from higher elevations [45]. In North America, *G. esculenta* toxicity has been reported both east and west of the Rocky Mountains [46].

Systems Approach to Signs, Symptoms, and Complications

Clinical findings of *G. esculenta* toxicity are varied. Symptoms are typically delayed for

4–12 h, with reported onset ranging from 2 to 48 h. Latency variations may be partially explained by variations in the concentrations of the different mushroom toxins [1, 47]. The gyromitrin syndrome normally starts with GI symptoms, including abdominal pain and bloating, nausea, vomiting, and occasionally watery or bloody diarrhea; it can be accompanied by headache, myalgias, and fever. Hemolysis, methemoglobinemia, neurological complications, and hepatorenal failure may follow, though most patients manifest only GI symptoms and make a complete recovery within several days. In severe toxicity, GI distress progresses to neurologic, hepatic, and renal dysfunction. An asymptomatic interval between resolution of GI symptoms and the onset of neurologic or hepatorenal toxicity may occur. A high index of suspicion is warranted for severe, protracted illness when caring for gyromitrin-exposed patients [1].

Systemic Effects of Gyromitrin

The GI effects of gyromitrin poisoning can last for several days, with excessive fluid losses causing hypovolemia, hypotension, shock, and acidosis. Patients may develop tachycardia and hypotension secondary to hypovolemia from GI losses. Cardiovascular instability may indicate significant multiorgan dysfunction or shock. Neurologic effects appear later, often after resolution of gastric complaints, with or without an asymptomatic period. Patients may report headache, dizziness, or vertigo and exhibit ataxia, seizures, coma, delirium, or labile emotions.

Hepatic failure usually develops within 48 h of ingestion, if at all, and is manifested by elevated transaminases, coagulopathy, and jaundice. Abdominal examination may reveal right upper quadrant tenderness. Biopsy samples of rat liver and kidney tissue after death from gyromitrin poisoning reveal discoloration of tissue, inflammatory changes, and focal necrosis [47].

Infrequently, renal failure develops as a result of hemolysis, rhabdomyolysis, or prolonged hypotension [48]. Renal failure may occur as a

result of a gyromitrin-induced hepatorenal syndrome. Rhabdomyolysis and diffuse myalgias are possible.

Hypoglycemia and electrolyte abnormalities may develop from significant GI losses. Fever is a manifestation of systemic inflammatory response or a consequence of hepatic injury.

Gyromitrin induced oxidative stress may precipitate intravascular hemolysis and methemoglobinemia. Hemolysis can be assessed by measuring plasma free hemoglobin, haptoglobin, and hemoglobinuria. Significant hemolysis may cause splenomegaly. The skin may appear jaundiced (from hepatotoxic effects), pale (from dehydration, hypovolemia, or hemolysis), or cyanotic (from methemoglobinemia). Methemoglobinemia should be suspected in any patient who develops cyanosis unresponsive to supplemental oxygen. Although the effects and clinical findings from methemoglobinemia do not correlate well with cooximetry-derived MetHb concentrations, most patients develop significant clinical manifestations at MetHb levels greater than 30%. Methemoglobinemia is discussed in detail in another chapter.

Diagnosis

There is no readily available laboratory assay to confirm the presence of gyromitrin in either mushroom or biological samples. A history of *G. esculenta* consumption greatly assists the diagnosis and management of gyromitrin poisoning.

Differential Diagnosis of Gyromitrin Poisoning

Poisoning from other mushroom toxins (e.g., amatoxin, coprine, ibotenic/muscimol)
Bacterial food poisoning
Other toxic ingestions (e.g., acetaminophen, salicylate, iron, isoniazid, organophosphates)
Methemoglobinemia from non-mushroom source (e.g., benzocaine)
Gastritis/gastroenteritis
Biliary disease/cholelithiasis

(continued)

Hepatitis/fulminant hepatic failure
Sepsis
Encephalopathy or seizure disorder
Hydrazine (monomethylhydrazine) poisoning
from nonmushroom source (e.g., rocket
fuel)

Laboratory testing should include liver, renal, and metabolic panels; complete blood counts; creatine kinase; coagulation profiles; and methemoglobin fraction, serum haptoglobin measurement, and plasma free hemoglobin levels. Gyromitrin concentrations can be quantitated by gas chromatography–mass spectrometry but have not been shown to correlate with clinical status and are not available in a timely fashion [49].

Patients should be placed on a cardiac monitor and have vital signs and oxygen saturation assessed frequently. Pulse oximetry utilizes only two wavelengths and cannot reliably differentiate between different hemoglobin species. Cooximetry testing is required to accurately quantify methemoglobin concentration. This is discussed further in ► Chap. 30, “Toxicant-Induced Hematologic Syndromes.”

Treatment

Treatment is mainly supportive, with emphasis on controlling gastroenteritis and replacing fluid and electrolyte losses. Patients typically present at least 4 h after ingestion, which limits the utility of GI decontamination. If patients present within 1 h of ingestion, however, activated charcoal theoretically may be beneficial (Level of Evidence [LoE] III). However, there are no studies to indicate that it alters outcome. If the decision is made to administer activated charcoal, it must be done with caution in patients whose ingestion may result in seizures or altered mental status. Cathartics are not indicated. All symptomatic patients should be admitted for supportive care and treatment.

Antidotes

Methylene Blue

All patients with clinically significant signs or symptoms of methemoglobinemia (or MetHb levels >30%) should be treated with supplemental oxygen and methylene blue, unless contraindicated (LoE II-2). The dose of methylene blue is 1–2 mg/kg by intravenous push. Reversal of symptoms is expected to occur within 15 min. If necessary, a second dose can be administered, with a maximal total dose of 7 mg/kg. At higher doses, methylene blue can induce oxidative stress and worsen methemoglobinemia. Methylene blue is contraindicated in patients with known glucose-6-phosphate dehydrogenase deficiency because of increased risk of methylene blue–induced hemolysis [50]. If clinically indicated, such patients should undergo exchange transfusion to correct methemoglobinemia. The treatment of methemoglobinemia is discussed in ► Chap. 30, “Toxicant-Induced Hematologic Syndromes,” and the clinical pharmacology of methylene blue is reviewed in another chapter.

Folinic Acid (Leucovorin)

Hydrazines inhibit the conversion of folate to its active form, and patients should benefit from receiving the active formulation (folinic acid or leucovorin) based on treating other types of hydrazine poisoning (LoE III). The usual dose is 5–15 mg/day intravenously, intramuscularly, or orally for 5–7 days. Higher doses (≤ 1 mg/kg intravenously every 4 h) can be given for severely poisoned patients. Because the inhibition of dihydrofolate reductase is transient, it is generally thought that after 24 h folate can replace folinic acid treatment.

Thioctic Acid and *N*-Acetylcysteine

A historic case series mentions the use of thioctic acid (α -lipoic acid) in the successful treatment of *G. esculenta*–poisoned patients [51]. This compound, similar to *N*-acetylcysteine, is reported to have antioxidant effects. Although there is a theoretical advantage to using these compounds, to date there are no studies showing improved clinical outcome. *N*-acetylcysteine was shown to be

ineffective at reversing methemoglobinemia produced by other oxidants in human volunteers [51, 52]. Neither thioctic acid nor *N*-acetylcysteine is recommended.

Pyridoxine

The use of pyridoxine (vitamin B₆) has been shown to limit the severity of hydrazine-induced neurologic dysfunction from isoniazid and gyromitrin [20, 53–57] (LoE II-3). The optimal dose for gyromitrin-induced neurotoxicity is unknown; recommendations range from 1 to 70 mg/kg [52]. The empirical intravenous administration of 5 g of pyridoxine to adult patients who convulse after ingesting an unknown quantity of isoniazid or who fail to respond to conventional anticonvulsant therapy is well established [57] (LoE III). Some have recommended giving this dose to gyromitrin exposed patients with seizures [1].

It seems reasonable to administer 25 mg/kg of pyridoxine intravenously once to all patients with known or suspected acute gyromitrin toxicity and to repeat doses if seizures occur or continue. If the patient has seized, 70 mg/kg (up to 5 g) should be given (LoE III). Administration of pyridoxine at doses greater than 500 mg/day for extended periods (≥ 6 months) is associated with the development of sensory neuropathy and other adverse effects but should not occur with short-term use [56, 58, 59]. The clinical pharmacology of pyridoxine is discussed in ► Chap. 163, “Pyridoxine.”

Other Treatments

Hemodialysis

Gyromitrin-induced renal failure should be managed in a standard fashion, including the use of hemodialysis. Usual guidelines for initiating hemodialysis in acute-onset renal failure should be followed.

Intravenous Fluids and Serum Alkalinization

Patients may develop significant dehydration secondary to GI losses and decreased fluid intake. Barring contraindications, aggressive fluid resuscitation should be provided to replace fluid

deficits, compensate for ongoing losses, and ensure adequate urine output (>0.5 mL/kg/h). Insertion of a urinary catheter may help assess urine output accurately. Hypovolemia should be managed with normal saline or lactated Ringer's solutions, with close monitoring of electrolytes and renal function. Rhabdomyolysis can be treated with urinary alkalization (LoE II3), as well as hydration, with a goal of a urine pH > 6.5 (LoE III) to help prevent the renal tubular deposition of myoglobin–Tamm-Horsfall protein complexes and acute renal failure [60]. Urinary alkalization can be accomplished by placing 150 mEq of sodium bicarbonate in 1 L of 5% dextrose in water, with an infusion rate of 200 mL/h in adults. Adding this amount of sodium bicarbonate to saline-containing fluids could produce hypernatremia. Urinary alkalization by this technique is best accomplished if the patient is not hypokalemic, which should be anticipated because bicarbonate administration will reduce serum potassium.

Treatment of Seizures

Treatment of gyromitrin-induced seizures includes the administration of benzodiazepines and pyridoxine, if necessary barbiturates (except, perhaps, phenobarbital, as discussed below) and propofol can be administered. These agents are GABA-agonists that decrease neuronal excitation. Pyridoxine overcomes the gyromitrin-induced inhibition of GABA synthesis (see Fig. 3). Benzodiazepines bind to the GABA_A chloride channel, increase GABA binding to its receptor, and increase the rate of GABA chloride channel opening. Barbiturates and propofol enhance GABA's actions at GABA chloride channels by prolonging the duration the channel remains open. At high concentrations, some barbiturates can directly open GABA chloride channels. Phenobarbital induces P-450 enzymes and increases the microsomal metabolism of gyromitrin, theoretically causing more hepatotoxicity [16]. The use of phenobarbital in the treatment of a gyromitrin-poisoned patient is therefore not recommended.

Phenytoin blocks voltage-gated sodium channels and inhibits the spread or propagation of

seizure activity but does not increase GABA concentrations within the CNS [61]. This mechanism is effective at preventing the spread of abnormal focal CNS electrical activity but is not expected to abort the diffuse neuronal involvement in gyromitrin-induced seizures. Therefore, the use of phenytoin is not recommended.

Vitamin K

Gyromitrin-induced hepatotoxicity can decrease vitamin K–dependent coagulation factors (factors II, VII, IX, X and proteins C and S). Pharmacologic correction for this effect can be administered in the form of vitamin K, at doses of 0.5–10 mg intravenously, intramuscularly, or orally, depending on the severity of the hepatotoxicity. A dose of only 0.5 mg intravenously should be used for patients requiring medical anticoagulation because reversal of vitamin K effects, which are long lasting, can be difficult to overcome [62]. The prophylactic use of vitamin K in patients with hepatotoxicity but not coagulopathy is controversial and not recommended.

Observation Time

Patients presenting after known or suspected *G. esculenta* ingestion should be observed clinically for at least 12 h after ingestion. Asymptomatic or minimally symptomatic patients can be discharged home if they have adequate support, outpatient follow-up, and instructions to return if symptoms progress. A regional poison control center may be able to assist with telephone follow-up. All patients with any of the following should be admitted to the hospital: signs or symptoms of toxicity (gastroenteritis, liver or renal dysfunction, seizures); significant comorbidities (cardiac disease or renal failure); and those at age extremes. Severely ill patients need intensive monitoring and care.

Special Populations

Theoretically, patients with smaller body surface areas (i.e., children and small adults) or significant comorbidities (i.e., hepatitis, anemia,

cardiac disease) are at increased risk for toxicity. A pregnant patient who ingests *G. esculenta* may place the fetus at risk due to maternal dehydration, shock, hepatotoxicity, methemoglobinemia, and other sequelae of gyromitrin poisoning. The treatment of pregnant patients should focus on the mother, given the potential benefits to fetal and maternal outcome. The teratogenic and embryotoxic risks of *G. esculenta* are unknown.

Patients with glucose-6-phosphate dehydrogenase deficiency are at increased risk for hemolysis. They may develop significant hemolysis, anemia, methemoglobinemia, and hypovolemic shock from either gyromitra poisoning or the use of methylene blue.

Indications for ICU Admission in Gyromitrin Poisoning

Hemodynamic compromise
Neurologic instability (coma or seizure)
Hemolysis (especially in patients with glucose-6-phosphate dehydrogenase deficiency)
Significant methemoglobinemia (e.g., dyspnea, tachypnea, dysrhythmia, confusion, seizures)
Toxicity in patients with significant comorbidity (e.g., acute coronary syndrome, renal failure)
Severe gastrointestinal symptoms with significant fluid imbalance

Key Points in Gyromitrin Poisoning

Gyromitrin can lead to significant morbidity and death.
Clinical onset generally in 6–12 h.
Gastrointestinal symptoms predominate early.
Most patients develop gastrointestinal complaints only and recover within several days. A transient asymptomatic period may occur.
Progression to hepatorenal or neurologic disease (or both) within 48 h may occur.
Hemolysis, methemoglobinemia, hepatorenal failure, jaundice, seizures, and coma can occur.

Criteria for ICU Discharge

Resolution of hemodynamic instability.
 Resolution of end organ damage (e.g., stabilization of comorbidities).
 Correction of fluid/electrolyte derangements, hemolysis, and/or methemoglobinemia.

Important Points Regarding Gyromitrin Poisoning

Acetylation status can determine neurological and hepatic effects.
 Oxidative stress can result in hemolysis and methemoglobinemia.
 Inhibition of histaminase can result in severe gastroenteritis.
 Inhibition of GABA synthesis may result in seizures.

Common Errors in Treating Gyromitrin Poisoning

Failure to consider the diagnosis.
 Failure to recognize potential severity of poisoning.
 Failure to recognize methemoglobinemia.
 Interpreting asymptomatic interval as Non-poisoning.
 Failure to identify patients with G6PD deficiency.
 Treating G6PD-deficient patients with methylene blue.
 Giving excessive or prolonged pyridoxine.

While critical care physicians commonly encounter cases of life-threatening drug and pharmaceutical toxicity, their exposure to significant plant and herbal toxicology is likely to be a rare occurrence. Poison center data indicate that calls related to plant ingestion are actually quite common but that the vast majority are not serious [1, 2].

However, there are a number of important plants and herbal products that a critical care physician should be aware of as having the potential for serious toxicity, and even death. The following chapter will highlight these plants in particular. Some types of plants and their effects are dealt with in greater detail in dedicated chapters of this book. It can be said that the level of evidence for therapeutic interventions in plant toxicology is low and are overwhelmingly case report/case series based. Randomized clinical trials are rare.

Also worthy of note is the obvious geographic variance in the distribution of plants around the world. This chapter will focus on the well-known poisonous plants and herbs, and it will not go into detail on their distribution, identification, or appearance. Identification of a plant suspected of causing poisoning or toxicity is obviously critical

e-mail: Philip.Aplin@sa.gov.au

in being able to determine the possible clinical course and management. In general, common names should not be relied upon for identification. Common names of plants are often confusing, and very different plants may have very similar common names (e.g., *Atropa belladonna* known as deadly nightshade and *Solanum nigrum* known as black nightshade). The use of a plant's botanical name will clarify any potential confusion. The best way to identify a plant is for as much of the plant as possible to be brought in with the patient, digitally photographed, and the image sent to an expert botanist via the regional poison center.

Exposure to plants will of course vary depending on geographic location, but it can be generalized that serious poisoning from plants is a far greater problem in the developing than the industrial world. For example, yellow oleander poisoning (*Cascabela thevetia*) is a major cause of death due to deliberate self-harm in Sri Lanka [3]. Exposure to plants can occur unintentionally as commonly seen in children exploring their environment or adults mistakenly thinking a toxic plant is edible. When an adult undertakes deliberate ingestion of a toxic plant, it is far more likely to result in serious clinical effects than accidental exposures in a child. Deliberate plant ingestion by an adult may be for recreational, medicinal, or self-harm intent. Estimation of an ingested dose or toxic amount of plant material is often extremely difficult due to variation in toxic concentrations between species, part of a plant, location, and time of the year. Some plants are also not uncommonly ingested as teas, which is effectively a hot water extraction of plant material.

The following table indicates the main plant/plant groups that will be covered in this chapter. They are grouped according to their main toxic component or mechanism of action. It is not a complete list of toxic plants, and it is important for an acute care physician to be aware of the toxic plants and herbs present in their own local environment.

The following table introduces most of the plants to be discussed in this chapter:

Group	Toxin	Plant's botanical/ common name
1. Cytotoxins	(i) Cytotoxic toxalbumins	<i>Ricinus communis</i> /castor bean <i>Abrus precatorius</i> /rosary pea
	(ii) Colchicine	<i>Colchicum autumnale</i> /autumn crocus <i>Gloriosa superba</i> /glory
	(iii) Cyanide	<i>Prunus</i> spp. and <i>Rosaceae</i> spp./apricot, bitter almond
2. Anticholinergic	(i) Atropine/scopolamine/hyoscine	<i>Atropa belladonna</i> /deadly nightshade <i>Datura stramonium</i> /Jimsonweed <i>Brugmansia</i> spp./angel's trumpets <i>Duboisia</i> spp./corkwood tree
3. Digoxin-like alkaloids	Thevetin	<i>Cascabela thevetia</i> /yellow oleander
	Oleandrin	<i>Nerium oleander</i> /common oleander
	Digitoxin	<i>Digitalis purpurea</i> /foxglove
	Convallatoxin	<i>Convallaria</i> spp./lily of the valley
	Cerberin	<i>Cerbera manghas</i> /sea mango
4. Sodium channel effects	Aconitine	<i>Aconitum napellus</i> /monkshood or wolfsbane <i>Delphinium</i> spp./larkspur
	Veratridine	<i>Veratrum</i> spp./false hellebore
	Grayanotoxins	<i>Rhododendron</i> spp.
	Taxines	<i>Taxus</i> spp./yew

(continued)

Group	Toxin	Plant's botanical/ common name
5. GABA antagonists	Cicutoxin	<i>Cicuta virosa</i> /water hemlock
		<i>Oenanthe crocata</i> /hemlock water dropwort
6. Nicotinic receptor effects	Coniine	<i>Conium maculatum</i> /poison hemlock
	Anabasine	<i>Nicotiana glauca</i> /tree tobacco
	Cytisine	<i>Laburnum</i> spp./golden chain
7. Hepatotoxins	Pyrrolizidine alkaloids	<i>Symphytum</i> spp./comfrey
	Thujone	<i>Mentha pulegium</i> /pennyroyal
	Catechins	<i>Camellia sinensis</i> /green tea
	Hypoglycemic agents	<i>Blighia sapida</i> /akee
		<i>Atractylis gummifera</i> /blue thistle or chardon a glu
8. Oxalate toxicity	(i) Insoluble oxalates	<i>Philodendron</i> spp./fruit salad plant
		<i>Colocasia</i> spp./elephant ear
		<i>Dieffenbachia</i> spp./dumb cane
		<i>Zantedeschia aethiopica</i> /arum lily
	(ii) Soluble oxalates	<i>Rheum</i> spp./rhubarb
		<i>Carambola</i> spp./star fruit
9. Dermatologic/ocular toxins		<i>Euphorbia</i> spp./spurges
		<i>Toxicodendron</i> spp./poison ivy and rhus
10. Miscellaneous		<i>Cleistanthus collinus</i> /oduvan

GABA gamma amino butyric acid, *spp.* species

Treatment Summary

Treatment for most plant poisoning is symptomatic and supportive. Gastrointestinal decontamination has not been studied specifically in plant poisoning, and a risk assessment should be made on a case-by-case basis. Many significant plant poisonings are accompanied by prominent gastrointestinal (GI) disturbance and potentially by a rapid decline in conscious state or other aspiration risk which clearly should be kept in mind when considering agents such as activated charcoal. The administration of activated charcoal has not been shown to improve outcome in most plant-poisoned patients.

Antidotes have a limited but important role in some cases of plant toxicity. Physostigmine has a place in reversing the effects of serious anticholinergic poisoning. Cyanide antidotes may be indicated in ingestions of large quantities of cyanogenic-containing plant material, and there is good evidence to support the use of digoxin immune Fab in cardiotoxicity from oleander poisoning [4] (Grade I data). All these will be covered in more detail in this and later chapters of this book.

Cardiac Glycosides

Poisonings from plants containing digoxin-like alkaloids are one of the most important potentially life-threatening presentations that an acute care physician may be faced with. The clinical features are similar to pharmacologic digoxin poisoning, and the management should be thought of along the same lines including the use of digoxin Fab in cases of serious toxicity. Important plants that contain cardiac glycosides are listed below:

- Common oleander (*Nerium oleander*)
- Yellow oleander (*Cascabela thevetia*)
- Lily of the valley (*Convallaria majalis*)
- Foxglove (*Digitalis purpurea*)

- Sea mango (*Cerbera manghas*)
- Odollam tree (*Cerbera odollam*)
- Red squill (*Urginea maritima*)
- Christmas rose (*Helleborus* spp.)

Cardiac glycosides (bufenolides) derived from toad skin secretions are also found in Chinese herbal products such as Chan Su.

These toxins act like digoxin in blocking cellular Na^+/K^+ ATPase resulting in increased vagal tone and intracellular sodium and calcium flux causing late depolarizations, increased automaticity, and hyperkalemia. The clinical manifestations feature GI upset and cardiac dysrhythmias, typically bradycardia, varying degrees of heart block and ventricular dysrhythmias. The most important biochemical finding is hyperkalemia caused by decreased intracellular potassium transport, a marker of serious toxicity. There may be some cross-reactivity of plant digoxin-like glycosides with laboratory digoxin assays, depending on the assay technique [4], but the level will not correlate with the degree of toxicity, and patients should be managed according to clinical presentation. The amount of plant material required to cause toxicity varies widely between plants.

Ingestion of a small number of seeds of yellow oleander (*Cascabela thevetia*) can cause death in an adult. Yellow oleander toxicity has been studied to a greater degree than any other plant poisoning. This is due to an epidemic of intentional yellow oleander seed ingestion as a method of suicide in Sri Lanka since the 1980s [5]. Such was the scale of the problem that a randomized controlled trial of digoxin Fab in yellow oleander poisoning was undertaken in Sri Lanka. This study showed that digoxin Fab was effective in restoration of sinus rhythm more quickly and in more patients than the control group [4]. Another randomized placebo-controlled study undertaken in Sri Lanka suggested potential benefit of multidose activated charcoal [6] (Grade 1 data).

Good supportive care is an essential accompaniment of any use of an antidote. Given the potential benefit of multidose activated charcoal, it follows that a single dose of charcoal should be given to alert patients with early presentation, meaning within the first hour or two post-

ingestion (Grade III recommendation). Severe hyperkalemia, particularly if accompanied by EKG changes, should be treated by conventional methods if digoxin Fab is not immediately available. Calcium has traditionally been considered to be contraindicated in digoxin poisoning; however, this is controversial and discussed in other relevant chapters in this book. Atropine can be given for severe bradycardia and AV block, and cardiac pacing is appropriate if bradycardia is refractory, though this may be ineffective. Ventricular dysrhythmias appear to be relatively uncommon in yellow oleander toxicity [7]. In the absence of anti-digoxin Fab, lidocaine may be tried along with standard American Heart Association Advanced Cardiac Life Support (ACLS) principles. Cardiopulmonary bypass or venoarterial extracorporeal membrane oxygenations are indicated as in other cases of toxin-induced cardiac arrest or severe hemodynamic instability resistant to other treatment. A more detailed discussion of plant cardiac glycoside poisoning is contained in a separate chapter of this book.

Cyanogenic Plant Toxicity

Cyanogenic glycosides are principally contained in the plant family *Prunus* that contains the well-known species apricot, bitter almond, cherry, plum, and pear. The seeds or kernels of these plants contain the toxin, amygdalin, also known commercially as Laetrile. When metabolized by the enzyme emulsin (also contained in the seeds and present in the gastrointestinal tract (GIT)), amygdalin releases cyanide [8] that can be absorbed systemically and cause cyanide toxicity with sufficient dose. Reports of clinically significant cyanide toxicity from plants most commonly involve excessive consumption of apricot and bitter almond kernels, which have been used as an alternative cancer therapy [9]. The effects of cyanide and clinical manifestations of cyanide poisoning are well known: dyspnea and metabolic features of a severe raised anion gap lactic acidosis due to cellular inhibition of oxidative phosphorylation. Central nervous system (CNS) effects of headache, confusion, seizures, and

coma, as well as cardiovascular effects of tachycardia and hypertension, progressing to bradycardic and shock, are also classically described. Treatment includes supportive care, consideration of GI decontamination with activated charcoal with airway protection by an endotracheal tube given the potential for rapid CNS deterioration in significant ingestions and antidote therapy. However, while of theoretical benefit if administered within the first hour after ingestion, activated charcoal has not been shown to alter the outcome in these patients. The antidote options are (1) sodium nitrite/thiosulfate combination, (2) high-dose hydroxocobalamin (vit B-12 precursor), or (3), rarely, Kelocyanor. In Germany 4-aminophenol is commonly used as methemoglobin producer in the treatment of cyanide poisoning. In one pediatric case series of cyanide poisoning from apricot kernel ingestion, all 13 patients had a good recovery [10]. All underwent gastric lavage and received activated charcoal. Nine patients had a lactic acidosis treated with sodium bicarbonate. Four required mechanical ventilation, hypotension in two, coma in two, and convulsions in one. Six patients received antidote treatment. Detailed consideration of these antidotes and cyanide poisoning is contained in other chapters of this book.

Plants Containing Insoluble Oxalate

Severe local mucosal irritation from contact with plant material containing insoluble oxalate crystals is the most common plant exposure reported to some poison centers [11]. This is because these plants are commonly found indoors and available to be ingested by young children exploring their environment.

The plants with the potential for this toxicity belong to the *Araceae* family. They are numerous and include the fruit salad plant (*Philodendron* spp.), elephant ear (*Colocasia* spp.), dumb cane (*Dieffenbachia* spp.), and the arum lily (*Zantedeschia aethiopica*).

The oxalate crystals are packaged in spear-like raphides within an injectable cell that releases the crystals and other enzymes into the mucous

membranes when the leaf of the plant is bitten [12]. The effect is severe local pain and possible swelling, but systemic oxalate toxicity is not observed. The pain associated with exposure to even small amounts of these plants typically limits further ingestion. Hence, the majority of cases are minor featuring significant oral discomfort that settles with local cooling and analgesia. The potential exists for more severe pharyngeal and laryngeal injury if larger quantities of plant material are chewed and swallowed and clinical signs of severe mucous membrane swelling, inability to swallow, dysphagia, and stridor should raise the possibility of potential upper airway obstruction. Eye exposures require irrigation and may require evaluation for corneal injury.

Soluble oxalates contained principally in the leaves of plants such as rhubarb have the potential to be absorbed from the GIT and cause deposition of calcium and magnesium oxalate crystals in the kidney with resulting hypocalcemia, hypomagnesemia, and renal impairment. This is a problem seen principally in animals not humans.

Dermatologic and Ocular Irritants

Spurges: This diverse group of plants has a common feature in producing a milky white sap that causes severe eye pain on topical exposure with a keratoconjunctivitis that can result in desquamation of the corneal epithelium and secondary uveitis. However, with good eye care as in a chemical eye injury and ophthalmology follow-up, the outcome is good, and the cornea generally heals without scarring [13].

Poison oak, *Rhus* spp., and poison ivy: Many plants may cause a variety of skin reactions. However, members of the *Toxicodendron* family, poison ivy, poison oak, and other *Rhus* trees are notorious for causing a severe, and often delayed, onset hypersensitivity dermatitis due to contact with urushiol compounds present throughout these plants. Depending on the individual's sensitivity, the time of onset varies from hours to a week after exposure. Treatment involves topical and oral steroids with resolution typically taking 10–14 days [14].

Nicotine-Like Toxins

Poison hemlock (*Conium maculatum*) is a widely distributed plant found in diverse settings, especially in wooded areas, along waterways, ditches, and roadsides. It can be mistaken for other edible plants in the same family such as wild carrot, parsley, and fennel. The distinguishing feature of poison hemlock is the purple spots on the stems and characteristic unpleasant “mousey” odor when crushed.

The principal toxin contained in poison hemlock is coniine which is structurally similar to nicotine and acts by activating, then blocking, nicotinic receptors throughout the nervous system [4, 15]. As these receptors are found in the parasympathetic and sympathetic nervous system and at the neuromuscular junction, the clinical manifestations are potentially diverse, but the main threat to life is respiratory muscle paralysis and CNS depression resulting in respiratory failure and death without appropriate supportive care. Deaths have been reported in Australia due to mistaken identity [16], and most famously Socrates is thought to have been poisoned and died after being forced to drink a concoction of poison hemlock. Poison hemlock is described in more detail in the chapter devoted to this plant.

There are a number of other plants with the potential for causing similar toxicity due to the action of nicotine-like toxins. These include tobacco (*Nicotiana tabacum*), wild tobacco (*Nicotiana glauca*), and golden chain (*Laburnum* spp.). Treatment is mainly supportive, particularly of ventilation, and while atropine may improve bradycardia and hypotension, it will not reverse the neuromuscular effects. Charcoal is not recommended without airway protection due to the propensity for CNS depression and seizures in these cases.

GABA Receptor Antagonists

Water hemlock (*Cicuta virosa*) (Fig. 1).

This is a well-known plant in the US and Europe and is also known as cowbane. The principal toxin is cicutoxin which is found throughout

Fig. 1 *Cicuta virosa* (Original book source: Prof. Dr. Otto Wilhelm Thomé, *Flora von Deutschland, Österreich und der Schweiz*, 1885, Gera, Germany. This image is in the public domain. Accessed at: http://biolib.mpgz.mpg.de/thome/band3/tafel_056.html)

the plant, but particularly in the roots. The plant may be mistaken for a wild variety of parsnip and accidentally ingested. Only small quantities of root are required to cause potentially serious toxicity [17]. Cicutoxin is a potent pro-convulsant, probably mediated by GABA receptor antagonism in the brain. As a result its main clinical effect is seizure activity, which may be resistant to standard anticonvulsant therapies such as benzodiazepines due to their reliance on GABA [18]. Following ingestion, GI upset is common followed soon after by sweating, salivation, confusion, and status epilepticus with the potential for all of the associated complications of prolonged seizures, including acidosis, rhabdomyolysis, renal failure, and hyperthermia. Treatment is supportive with aggressive and multiple anticonvulsant medications often required in an intensive

care setting to control seizure activity. The treatment of such seizures is discussed in detail in the ► Chap. 20, “Toxicant-Induced Seizures.” Due to the rapidity of seizure onset, GI decontamination with activated charcoal should only be considered once the airway is secured. Water hemlock poisoning is described in detail in the chapter devoted to this agent.

Hemlock water dropwort (*Oenanthe crocata*): Also known as “dead man’s fingers,” this plant is similar in appearance to poison hemlock and water hemlock and belongs to the same Apiaceae family. Ingestion of this plant is also usually due to mistaken identification of the roots/tubers as being edible. The clinical effects are similar to water hemlock poisoning, i.e., principally seizure activity. Treatment is supportive as outlined in water hemlock poisoning.

Sodium Channel Toxins

Aconitine: Mainly encountered as herbal preparations, aconitine is a potent alkaloid derived from all parts of the aconitum plant (*Aconitum napellus*) also known as wolfsbane or monkshood, a small blue/purple flowering plant. The highest concentration of aconitine is found in the roots [19]. This is a widely used herbal remedy, particularly in Chinese traditional medicine. Poisoning may occur through ingestion or topical absorption [20]. Aconite produces its effects by opening of voltage-sensitive sodium channels in the myocardium, nerves, and muscle leading to prolonged depolarization and premature excitation [21]. Clinical features occur soon after ingestion. GI symptoms are common if taken orally, but the most characteristic symptoms are paresthesias and numbness of the lips and mouth, limb and muscle weakness, bradycardia, hypotension, and a variety of cardiac dysrhythmias, the most lethal being ventricular tachydysrhythmias potentially leading to cardiac arrest [19]. These ventricular dysrhythmias can be resistant to antidysrhythmic drugs and cardioversion/defibrillation [19]. Treatment is supportive and should proceed along standard ACLS guidelines. In addition the use of extracorporeal cardiac support should be strongly

considered in cases of cardiac arrest or cardiogenic shock due to aconite poisoning.

Veratrum alkaloids: Plants belonging to the genus *Veratrum* or false hellebores and *Zigadenus* or death camas contain a number of veratrum alkaloids including veratridine that act on voltage-gated sodium channels to increase permeability to Na^+ and Ca^{++} [22]. Ingestion usually results from misidentification as an edible plant such as the common camas or sego lily. The main clinical effects following ingestion are vomiting, bradycardia, and hypotension [23]. Neurological symptoms are generally mild. Treatment is supportive involving fluids, atropine, and, in severe cases, vasopressor support.

Rhododendron: Similar toxins to aconitine and veratridine are present in *Rhododendron* spp., called grayanotoxins. Poisoning from these plants in humans is rare except for cases of toxic honey ingestion in Turkey made from nectar derived from *Rhododendrons*. The principal clinical effects are vomiting, bradycardia, hypotension, neuromuscular weakness, and paresthesias. Ventricular dysrhythmias and conduction blocks responsive to atropine have been noted in case reports [24, 25]. Treatment is supportive.

Yew (*Taxus* spp.): The yew tree is commonly found in cooler climates throughout the world and is characteristically found surrounding churches and graveyards in the United Kingdom. All parts of the tree are toxic apart from the soft fleshy aril of the fruit. However, the seed contained at the center of the fruit is toxic. The main alkaloid toxins are known as taxines A and B which act to alter sodium and calcium channel conductance in cardiac myocytes. It causes a delay in action potential depolarization rate similar to the effect of class I antidysrhythmics [26]. Yew also contains taxanes which are spindle poisons that are used as chemotherapeutic agents [27]. Ingestion of plant material typically causes GIT effects, but principally it is the cardiovascular effects that are the most important clinical manifestation. Initial bradycardia may be followed by QRS prolongation, ventricular tachycardia, hypotension, cardiogenic shock, and cardiac arrest. The yew leaves or needles are most commonly ingested either accidentally by children or deliberately by adults as it

is a well known and readily available toxic plant in some parts of the world. An estimated dose of around 50 g of yew needles in an adult has the potential for serious toxicity and death [28]. Management is essentially supportive using ACLS principles. Atropine may be useful in bradycardia, and cardiac pacing for severe conduction disturbances and digoxin Fab have been used in some cases [29] though there is no good evidence they are effective. Prolonged CPR and extracorporeal cardiac support may result in patient survival in cases of cardiac arrest or cardiogenic shock.

Anticholinergic Plant Toxicity

A number of plants contain anticholinergic compounds such as atropine, hyoscyne, and scopolamine that when ingested cause features of the anticholinergic toxidrome. These plants include Jimsonweed (*Datura stramonium*), deadly nightshade (*Atropa belladonna*), henbane (*Hyoscyamus niger*), and angel's trumpet (*Brugmansia* spp.), among others (Fig. 2).

Due to the fact that these plants are often deliberately ingested for their hallucinatory effects, they are relatively common plant poisonings encountered in emergency departments, and often more than one patient will present at a time. The anticholinergic toxidrome consists of hallucinations and delirium, pupillary dilation, dry flushed skin, tachycardia, hyperthermia, and urinary retention. Seizures and cardiac arrhythmias are uncommon. Injuries may be sustained due to the psychotic state inducing risk-taking behavior and self-harm. All parts of these plants contain tropane alkaloids in varying concentrations [30]. In the case of *Datura*, it is the seeds that are usually ingested, whereas with *Brugmansia* it is as a tea brewed from the leaves. Clinical effects develop rapidly in these later cases. Treatment of affected patients initially involves providing a reassuring low-stimulus environment, benzodiazepine sedation for agitation, and, in severe cases, consideration of the use of the antidote physostigmine, an anticholinesterase inhibitor that will effectively reverse the anticholinergic effects. Notably physostigmine has a

Fig. 2 *Brugmansia Feingold* (<https://commons.wikimedia.org/w/index.php?curid=142315> under a Creative Commons license)

much shorter half-life than the tropane alkaloids. Physostigmine also has potential value as a diagnostic agent in suspected cases of delirium due to anticholinergic plant poisoning. Decontamination using activated charcoal can be considered following a risk assessment on a case-by-case basis in early presenting cases. However, given the altered mentation exhibited by these cases, the risk of charcoal administration in patients with unprotected airways is potentially significant. Activated charcoal has not been shown to alter the outcome in these patients. Further, the anticholinergic toxidrome induced by these plants can be reversed by physostigmine. The usual intravenous dose is 2 mg over 2 min. The use of physostigmine in anticholinergic poisoning is discussed in greater detail in ► Chap. 23, “Anticholinergic Syndrome.” The clinical pharmacology of physostigmine is reviewed in ► Chap. 161, “Physostigmine.” Even in the absence of treatment, however, the clinical effects from these poisonings usually resolve within 24 h [31].

Cellular Poisons

Ricin: The castor bean plant (*Ricinus communis*) is the source of the potent biologic toxin ricin. It is derived from the seeds of the plant which have a characteristic variegated brown and black appearance and a hard outer shell. This shell must be broken for ricin to be released. Ricin is a cellular toxin that acts by inhibiting ribosomal protein synthesis [32]. The effects depend on the route of exposure. The toxicity of ricin by the inhaled or injected route is approximately 1,000 times greater than when ingested [33]. If swallowed whole without being chewed, the seeds will pass through the gut with no or only minor symptoms. When chewed, or deliberately crushed, ricin can be released but is probably poorly absorbed from the intestine. Even so, historically death has been reported with ingestion of as few as two seeds [34]. The effects following ingestion are principally gastrointestinal with the potential for significant fluid and electrolyte losses, and hepatic and renal dysfunction may also be found [35]. Parenterally injected ricin leads to multi-organ failure with an LD₅₀ in mice of 5–10 µg/kg [36], while inhaled ricin produces noncardiogenic pulmonary edema at tiny doses if the particle size reaches the lower airways [37].

Treatment of ricin poisoning is entirely supportive in all cases. Activated charcoal can be considered in recent ingestions. However, the administration of activated charcoal has not been shown to alter the outcome in patients who have ingested ricin. Ricin poisoning is covered in more detail in ► Chap. 114, “Toxalbumins.”

Abrin: The attractive red and black seeds, often made into necklaces and bangles, of the tropical/subtropical plant *Abrus precatorius* or rosary pea (Fig. 3) contain the potent toxin abrin which is very similar in structure and mechanism of action to ricin [38]. Similar toxicity can be expected if chewed or crushed seeds are ingested [39]. Abrin poisoning is discussed in detail in ► Chap. 114, “Toxalbumins.”

Colchicine: *Colchicum autumnale*, commonly known as autumn crocus or meadow saffron, is the plant source of the drug colchicine. Usually as a result of mistaken identification as the edible

Fig. 3 *Abrus precatorius* (rosary pea) Forest and Kim Starr – USGS plants of Hawaii

wild garlic plant *Allium ursinum*, ingestion of any part but most commonly the leaves of *Colchicum* can result in potential serious and fatal colchicine poisoning [40]. Colchicine is a well-known cellular poison preventing microtubular formation and inhibiting mitosis. High turnover organ systems such as the GI tract and bone marrow are preferentially affected. Hence, ingestion of sufficient quantities of the *Colchicum* plant will present in the same fashion, with initial GI symptoms, bone marrow suppression, and multisystem organ failure occurring in a dose-dependent fashion. Treatment is supportive. As recommended in ingestions of unknown or potentially serious amounts of colchicine tablets, activated charcoal should be administered to all cases as even small reductions in the amount of colchicine absorbed may affect outcome (Grade III recommendation). Multidose activated charcoal can be considered; however, there is no evidence that it enhances outcome in colchicine-poisoned patients and colchicine is not considered to be one of the toxins amenable to enhanced elimination by this treatment in a major position statement issued by major clinical toxicology societies (<http://www.clintox.org/documents/positionpapers/MultipleDoseActivatedCharcoal.pdf>). Colchicine toxicity may also occur from ingestion of tubers of the colchicine-containing plant *Gloriosa superba* or glory lily.

Plants Causing Hypoglycemia

Akee (Blighia sapida): This is the national fruit of Jamaica and commonly eaten. However, ingestion of the unripe fruit of this tropical plant is potentially deadly and the cause of “Jamaican vomiting sickness” characterized by GI distress, marked hypoglycemia, coma, convulsions, and liver dysfunction. The main toxin is hypoglycin A and acts by interfering with long-chain fatty acid metabolism. Hypoglycemia does not explain the whole clinical picture; other compounds may account for some of the CNS effects seen with akee poisoning [41]. Treatment is supportive plus intravenous dextrose.

Chardon a glu (Atractylis gummifera): Commonly known as blue thistle, it is a significant plant poison in North Africa due to misidentification with an edible plant, *Scolymus hispanicus* or Geumina. It also causes hypoglycemia along with CNS and hepatotoxicity due to atractyloside toxins that interfere with oxidative phosphorylation [42].

Miscellaneous

Cleistanthus collinus: Commonly known as oduvan, this important toxic plant has been responsible for many deaths in southern India due to deliberate ingestion as a method of self-harm [43]. All parts of the plant are toxic but mainly the leaves are ingested. The toxicity of the plant has been attributed to a number of complex compounds with the clinical effect being the characteristic metabolic derangement of a distal renal tubular acidosis manifest by a normal anion gap hypokalemic metabolic acidosis and also cardiac dysrhythmias, respiratory failure, and shock [44]. Management focuses on correction of hypokalemia and acidosis and cardiorespiratory support. Activated charcoal may be given with the usual considerations; however, it has not been shown to alter the outcome in these patients.

Herbs and Essential Oils

Herbal products are widely available over-the-counter products, the use of which has grown

enormously over the past 20 years. Consumers of alternative health products may not be aware of the potential side effects and toxicity of these agents or disclose that they are taking them to healthcare professionals. Varying regulations exist between countries controlling herbal products, but cases of miscalculation, adulteration, and contamination and lack of standardization are all reported in the literature. Herbal preparations may also include essential oils which are often concentrated extracts of plant material and potentially toxic in small volumes. Though the number of herbal preparations is huge, only the most important herbal product-related toxicity will be covered in this introductory chapter.

As the toxicity of herbal preparations often affects the liver, a good history of the potential use of these products is important in the workup of patients with otherwise unknown causes of liver dysfunction.

Pyrrolizidine alkaloids are contained in a number of plants and appear to be the causative toxins in cases of hepatic veno-occlusive disease associated with herbal preparations. The plant species containing these alkaloids include *Symphytum* (comfrey), *Heliotropium*, *Senecio*, and *Crotalaria*. The dose required to cause toxicity is difficult to define due to varying content in plant species and individual variation in susceptibility. The toxic effect is a form of sinusoidal obstruction similar to the hepatotoxicity seen with bone marrow transplantation [45]. Pulmonary damage is sometimes also seen. Presentations may range from an acute hepatitis to a more chronic picture resembling Budd-Chiari syndrome [46]. Hepatotoxicity has also been reported from the ingestion of green tea, particularly with more concentrated extracts and multicomponent forms [47], chaparral, germander, the Chinese herbal product Jin Bu Huan, clove oil, and pennyroyal oil (*Mentha pulegium*). Particularly in the case of pennyroyal oil-induced hepatotoxicity, the use of *N*-acetylcysteine may be beneficial as glutathione deficiency may enhance toxicity [48] (Grade III recommendation).

Other herbal toxins to note include:

	Potential for drug interactions and enhanced serotonergic effects
Yohimbe/ma huang	Sympathomimetic effects secondary to ephedrine
Wintergreen (oil of)	Salicylate toxicity
Eucalyptus oil	CNS depression and risk of aspiration
Clove oil	CNS depression, aspiration risk, and hepatorenal failure noted in pediatric case reports [49]

This is not a complete list, and practitioners should also be aware of the varying regulations and quality controls that exist for these products throughout the world when dealing with patients with potential toxicity from over-the-counter preparations.

Exposure to plants with anticholinergic properties can result in emergency department and intensive care unit (ICU) admissions due to hallucinations, delirium, agitation, seizures, hyperthermia, and rhabdomyolysis among other clinical manifestations of toxicity [1–3]. Alkaloid-containing plants of the *Solanaceae* (nightshade) family, especially *Datura* spp., have been used since antiquity as analgesics, hypnotics, aphrodisiacs, hallucinogens, and as herbal remedies. Homer likely referred to *Datura* in the *Odyssey* [4]. Dioscorides, in *De Materia Medica*, described dose-dependent *Datura* toxicity [5]. Cleopatra lured Caesar with this plant and Marc Antony’s troops suffered confusion and fatalities after eating the plant when retreating from Parthia in 38 AD. An outbreak of *Datura* poisoning occurred in colonial Virginia in 1676, during Bacon’s Rebellion [3]. In his work, *The History and Present State of Virginia*, Robert Beverly described behaviors consistent with anticholinergic delirium among soldiers who were sent “to quell the Troubles”:

The *James-Town* Weed (which resembles the Thorny Apple of Peru, and I take to be the Plant so call’d) is supposed to be one of the greatest Coolers in the World. This being an early Plant, was gather’d very young for a boil’d Salad, by some of the Soldiers sent thither, to quell the Troubles of Bacon; and some of them eat plentifully of it, the Effect of which was a very pleasant Comedy; for they turn’d natural Fools upon it for several Days: One would blow up a Feather in the Air; another wou’d dart Straws at it with much Fury; and another stark naked was sitting up in a Corner, like a

Monkey, grinning and making Mows at them; a Fourth would fondly kiss, and paw his Companions, and sneer in their Faces, with a Countenance more antick, than any in a *Dutch Droll*. In this frantick Condition they were confined, lest they should in their Folly destroy themselves; though it was observed, that all their Actions were full of Innocence and good Nature. Indeed, they were not very cleanly; for they would have wallow'd in their own Excrements, if they had not been prevented. A Thousand such simple Tricks they play'd, and after Eleven Days, return'd to themselves again, not remembering any thing that had pass'd. [6]

Unintentional outbreaks of anticholinergic delirium have occurred with poisoning from contaminated flour [7–9], when food has been prepared with berries mistaken for edible varieties [10–12], when leaves have been prepared in a salad [13], or when plant parts have otherwise been prepared in food [14–16], brewed in tea [17–20], or used as a herbal remedy [21, 22]. Outbreaks have also occurred due to recreational use as a hallucinogen [1, 2, 11, 17–19, 23–33]. Six hundred and ten single exposures to anticholinergic plants were reported to the National Poison Data System in 2014; most were unintentional (454 of 610 [74%]) [34]. Pre-teen children (≤ 12 -years-old) accounted for most exposures (381 of 610 [63%]) [34]. Most patients were not treated in a healthcare facility (419 of 610 [69%]) [34]. A minority of patients developed moderate clinical effects (80 of 610 total single exposures [13%] with 80 of 191 treated in healthcare facilities [42%]) or major clinical effects (8 of 610 total single exposures [1%] with 8 of 191 treated in healthcare facilities [4%]) [34]. No fatalities were reported [34]. This chapter will focus on patients with anticholinergic plant poisoning who require care in healthcare facilities, especially in the ICU. The term, anticholinergic in this chapter will be restricted to its common connotation which is antimuscarinic.

Anticholinergic Plants

Anticholinergic plants are members of the *Solanaceae* family. This family includes foods (e.g., tomatoes, potatoes, paprika, eggplants, red

peppers), tobacco, and ornamentals (e.g., petunias) [5, 35]. These plants grow in temperate and tropical climates and include the genera *Atropa*, *Datura*, *Duboisia*, *Hyoscyamus*, and *Mandragora* [36]. The pharmacologically active components are the tropane (belladonna) alkaloids: atropine (D,L-hyoscyamine) and scopolamine (L-hyoscyne). The L-isomer of atropine (L-hyoscyamine) is predominantly responsible for atropine's pharmacological action.

Atropa belladonna

Atropa belladonna, deadly nightshade, is perhaps the best known of the *Atropa* genus (Fig. 1). It is native to continental Europe and Great Britain and is cultivated in the United States as an ornamental [37, 38]. Its roots, leaves, and fruits contain tropane alkaloids, including 98% atropine with only small amounts of scopolamine [10, 21, 39]. It grows as a bush with purple-black berries. These berries, which contain as much as 2 mg of atropine per berry, may be mistaken for edible berries [10, 12].

Fig. 1 *Atropa belladonna* (Photo courtesy of Julian White © Rights remain with the Photographer)

Datura Species

Datura stramonium, also known as Jimson weed, locoweed, thornapple, and other common names, is the most geographically widespread of the potentially toxic *Solanaceae* [29] (Fig. 2). It is a large annual shrub with dark green ovate-oblong leaves and a white tubular flower that blooms from July to September, followed by the growth of a fruit consisting of a four-lobed, spiny pod [11]. Each of these pods contains 50–100 kidney-shaped seeds 2–3 mm in size that change from yellow to tan to black as they mature. All parts of the plant contain anticholinergic compounds, though the amounts of atropine and scopolamine can vary depending on the part of the plant, the age of the plant, and the time of year [38, 40–42]. Each seed contains about 0.05–0.1 mg of atropine, or about 6 mg per pod [2, 40]. *Datura stramonium* is used as a hallucinogen, commonly by ingesting the seeds, but also by smoking the leaves or brewing in a tea [2, 17, 18, 28, 29, 31–33, 43]. Accidental poisoning has occurred

Fig. 2 *Datura stramonium* (Photo courtesy of Robert French © Rights remain with the Photographer)

from use as an herbal tea or herbal therapy [11, 18, 41, 44, 45]. Young children have been poisoned after ingesting seeds when playing with the seed pod [46–48]. Fatalities have been reported [49, 50].

Angel's trumpet, or sacred *Datura*, is referred to variously as *D. sauveolens*, *D. candida*, *D. innoxia*, *D. meteloides*, *Brugmansia candida*, and *B. sauveolens* [19]. It grows wild throughout the southeastern United States, the Caribbean, and South America and is a common garden ornamental plant [24]. It is an evergreen bush 2–8 m high, with trumpet-shaped, purplish-to-white flowers measuring 20–50 cm that hang straight down [19, 24, 38, 51, 52]. Exposure is typically from use as a hallucinogen by brewing tea, ingesting the leaves and flowers, or steeping the leaves and blossoms in water and alcohol to yield a “magic drink.” Angel's trumpet may also be mistaken for a herbal tea, herbal remedy, or an edible plant [19, 22, 24, 27, 52–54].

Toxic effects of Chinese herbal medicines and Chinese proprietary medicines account for 0.2% of the acute medical admissions in Hong Kong [51]. Some are derived from *Datura* spp. that are native to south Asia and China [55], including *D. metel*, *D. innoxia*, *D. tabula*, and *D. fastuosa*. They are used to treat asthma, chronic bronchitis, seizures, psychosis, and pain [51]. Yangjinhua is made from the dried flowers of *D. metel*, containing the tropane alkaloids in the following proportion: 85% scopolamine and 15% atropine [55]. Yangjinhua may be smoked, given orally, or administered intravenously [55].

Duboisia Species

Duboisia hopwoodii, *D. leichhardtii*, and *D. myoporides*, known collectively as corkwood, are plants native to Australia [56]. These plants are farmed as a source of scopolamine and atropine [57, 58]. Occupational exposure to plant material has resulted in a syndrome characterized by mydriasis and cycloplegia dubbed “cork-eye” and intentional ingestion has resulted in systemic toxicity [59].

Fig. 3 *Hyoscyamus niger* from Kohler’s Medicinal Plants, 1887, Bera-Untermhaus, Germany (in public domain)

Hyoscyamus niger

Hyoscyamus niger, henbane, (Fig. 3) is a foul-smelling annual or biannual herb that is native to Europe and northern Africa but is also distributed widely in North America [38, 60, 61]. All parts of the plant, including the roots, leaves, and fruits contain atropine and scopolamine [38, 62]. It has been used intentionally as a hallucinogen and inadvertent poisoning has occurred when mistaken for parsnip [16].

***Mandragora* Species**

Mandragora species are widespread around the Mediterranean [15]. Historically, these plants were characterized by supposedly human-shaped or phallus-shaped roots, which were thought to have occult properties [35, 36]. However, in addition to the root, the leaves, seeds, and berries contain varying concentrations of tropane

alkaloids. Outbreaks of anticholinergic poisoning have occurred when this plant has been mistaken for an edible plant [63, 15].

The toxicity of *Mandragora*, commonly known as mandrake, should not be confused with that of *Podophyllum peltatum*, which is sometimes known by a similar common name, American mandrake. *Podophyllum peltatum* contains podophyllotoxin (see Chap. 71, “Antitubulin Agents: Colchicine, Vinca Alkaloids, and Podophyllin”) [64].

Fig. 4 Atropine [68]

Fig. 5 Scopolamine [69]

The tropane alkaloids, atropine and scopolamine, are responsible for the pharmacological and toxicological actions of anticholinergic plants (Figs. 4 and 5).

Atropine and scopolamine are rapidly absorbed from the gastrointestinal tract. Clinical effects typically occur within 5–10 min after the ingestion of teas and 1–3 h after ingestion of leaves or seeds [19, 70]. Slow dissolution of the plant parts, along with anticholinergic slowing of the gastrointestinal tract, prolongs absorption [28]. Unabsorbed alkaloids have been found in the stomach 24 h after ingesting anticholinergic plant parts and the anticholinergic effects last much longer than predicted by known absorption and elimination rates of pure atropine and scopolamine [2, 26, 28]. Atropine and scopolamine are widely distributed throughout the body.

Elimination is by hepatic metabolism and renal excretion. Twenty percent to 50% of atropine is excreted unchanged in the urine, in contrast to only about 1–5% of scopolamine [10, 11, 26, 71].

Pathophysiology of Toxic Effects

Atropine and scopolamine compete with the neurotransmitter acetylcholine at a common binding site on all five muscarinic acetylcholine receptor subtypes. Muscarinic acetylcholine receptors are located throughout the central nervous system, primarily in the brain, in organs innervated by the parasympathetic division of the autonomic nervous system, and in the skin at postganglionic, sympathetically innervated sweat glands.

Clinical Presentation and Life-Threatening Complications

Anticholinergic plants can cause central and peripheral manifestations of the anticholinergic syndrome (see Chap. 23, “Anticholinergic Syndrome”). Peripheral effects include mydriasis, flushing, tachycardia, dry skin, dry mouth, decreased gastrointestinal motility, urinary retention, and hyperthermia; central effects are usually hallucinations and delirium. Atropine and scopolamine block the cholinergic actions on the sphincter muscle of the iris and the ciliary muscle of the eye, resulting in mydriasis and loss of accommodation [72].

The severity and duration of clinical effects depend on the route, form (e.g., tea ingestion, flower/leaf smoking), and dose, with some variation in content among the different anticholinergic plants. The progression of symptoms can be related to the equivalent dose of atropine and scopolamine. Time to onset of clinical effects varies with the route and the plant involved, beginning within 5–10 min if a tea or broth is ingested or delayed for 1–3 h if seeds or leaves are ingested [19, 24]. Signs and symptoms may last several days (up to 11, in Beverly’s historical account) [2, 6].

Altered mental status is the most prominent and frequent manifestation, present in all 27 patients in one report [28]. More common CNS effects are restlessness, bizarre behavior, delirium, disorientation, and combative behavior; seizures and coma are unusual. Patients characteristically pick at imaginary objects in the air, on clothing, or on bed sheets and have fragmented, mumbling, rapid, and incomprehensible speech [2, 11]. Patients may be able to answer questions appropriately with one to two words, but their disorientation and confusion are revealed when responding in sentences. Severely affected patients may be mute [70]. Hallucinations or delusions were the most frequently reported adverse effect, occurring in 50% of 122 *D. stramonium* exposures that were reported in Texas between 1998 and 2004 [1]. Hallucinations commonly feature the family or friends, natural colors, simple objects, visual misperceptions, and the sensation of flying [11]. The hallucinations are sometimes perceived as small objects or people and described with the term Lilliputian, referring to the little people described in Jonathan Swift's *Gulliver's Travels* [16, 40, 73]. Auditory hallucinations are less common [11, 29, 53]. Patients are often amnesic for events, after recovering [11, 29, 53]. Particularly characteristic of belladonna alkaloid intoxication is undressing behavior, presumably due to the subjective symptoms associated with flushing and hyperthermia, combined with loss of inhibitions [24, 29, 70, 74]. Neurologic examination may reveal hyperreflexia, clonus, myoclonus, and sometimes dorsiflexor Babinski responses. Coma with decerebrate posturing [11, 29] or decorticate posturing has been reported [75, 76]. Neurological findings in the comatose patient may suggest focal lesions [76]. Convulsions and flaccid paralysis may occur in severe cases [24].

Cardiovascular abnormalities are ordinarily limited to sinus tachycardia; mild hypertension and widened pulse pressure are seen in some cases [19, 24, 25, 30, 54]. Mydriasis occurs early in intoxication and is often one of the last signs to resolve. Blurred vision and dilated pupils may present as the only manifestations of a minor exposure or from anisocoria following monocular contact with plant parts ("Gardener's mydriasis")

[27, 77]. Urinary retention and gut hypomotility may present as early or late complications. Vomiting may be present early, particularly with accidental ingestion of large amounts, such as in foods and teas [12, 20]. Dysphagia and dysarthria result from severe mouth and throat dryness. Renal insufficiency or failure may occur due to rhabdomyolysis and dehydration.

Complications of severe anticholinergic plant poisoning include aspiration pneumonitis due to loss of airway protection, particularly in patients with seizures [10, 52]. Severe agitation, myoclonus, and seizures, coupled with hyperthermia and dehydration, create a risk of rhabdomyolysis and resultant renal injury [3, 12, 78]. Delirium could put patients at risk of traumatic injury. There are few reports of death associated with anticholinergic plant ingestion [17, 49, 50, 54, 79].

Diagnosis

Anticholinergic plant poisoning is a clinical diagnosis. There are no routinely available tests that can be used to confirm ingestion of an anticholinergic plant. The diagnosis is made by obtaining a history, often from indirect sources, and performing a careful and complete physical examination. Resolution of delirium after administration of physostigmine is virtually diagnostic of anticholinergic toxicity.

Clusters of cases, such as simultaneous onset of symptoms in family or friends who have shared a meal, or the onset of the anticholinergic syndrome in a group of adolescents or young adults suggests the diagnosis [12, 15, 19, 20, 24, 25, 27, 30, 31, 33, 63]. Routine immunoassays for drugs of abuse and comprehensive drug screens do not detect the belladonna alkaloids. Qualitative and quantitative assays of blood, urine, hair, gastric contents, and plants by gas chromatography-mass spectrometry or thin-layer chromatography can detect atropine and scopolamine, but these assays are not routinely available [10, 24, 28, 49, 53, 70, 80, 81].

Nonspecific laboratory abnormalities that have been reported include transient elevations of lactate dehydrogenase, hepatic transaminases,

calcium, phosphorus, prothrombin time, and white blood cell count [19, 28, 29]. Serum creatine kinase levels, urinalysis, and renal function tests may reveal rhabdomyolysis, myoglobinuria, and renal failure. These findings may occur as a result of hyperthermia and/or agitation [3, 12, 82].

Sinus tachycardia is the typical electrocardiographic feature [16, 20, 40]. Mikolich reported electroencephalogram findings in six patients who presented after ingestion of *D. stramonium* seeds and who had no observed seizures. Diffuse slowing was seen in three of the patients, rhythmic bursts of high-voltage sharp waves in two, and marked loss of alpha activity one. These electroencephalograms returned to normal in all cases. The observed changes may be due to hyperthermia or to the antagonistic actions of toxic alkaloids on cholinergic pathways in the reticular activating system [29].

Differential Diagnosis

The differential diagnoses to be considered when faced with a comatose patient, a convulsing patient, or with a patient who is agitated, delirious, hyperthermic, and tachycardic includes toxic, metabolic, infectious, traumatic, and psychiatric causes. Common possibilities include overdose of pharmaceuticals with anticholinergic, sympathomimetic, or serotonergic properties; ingestion of recreational drugs; or ingestion of anticholinergic plants. Withdrawal syndromes, stroke, seizure, hypo- or hyperglycemia, fluid and electrolyte abnormalities, hepatic encephalopathy, hyperthyroidism, CNS infections, and psychoses must also be considered [2, 14, 16, 27, 40, 75, 76, 83, 84].

The presence of characteristic peripheral and central manifestations of anticholinergic toxicity may help differentiate anticholinergic plant poisoning from other potential diagnoses [40]. For example, hyperthermia and agitation may be seen with cocaine, amphetamine, or other sympathomimetic drug intoxications, or with serotonergic drug intoxications. However, these conditions typically cause diaphoresis. This is distinctly unusual for anticholinergics that typically produce dry axillae and dry mucous membranes. Ileus and

urinary retention are also characteristic peripheral findings. Undressing behavior, mumbling, rapid, incomprehensible speech, and visual hallucinations are characteristic of the central effects of anticholinergic toxicity and strongly support the diagnosis of anticholinergic toxicity.

Diagnostic studies that may be helpful in the differential diagnosis include blood glucose, urine drugs-of-abuse screening, complete blood cell count, serum chemistries, creatine kinase, transaminases, ammonia and lactate levels, salicylate and acetaminophen levels, thyroid function tests, brain imaging, and electrocardiograms. Lumbar puncture can be used for diagnosing or excluding CNS infection. CT scans may assist with evaluation of head trauma or CNS hemorrhage. With appropriate caution, a diagnostic trial of physostigmine may help establish the diagnosis of anticholinergic toxidrome and possibly avoid unnecessary diagnostic testing. Lack of response to physostigmine makes anticholinergic poisoning much less likely as a potential cause of delirium.

Treatment

A common scenario is an agitated, delirious patient being restrained by emergency or security personnel. Treatment priorities include, in some cases, protecting the airway to prevent aspiration and controlling agitation to prevent complications, such as hyperthermia, rhabdomyolysis, myoglobinuric renal tubular injury, and traumatic injury to the patient or to staff. Physical restraints may be needed but should be avoided for prolonged periods because of the risk of developing rhabdomyolysis. Should physical restraint be required, patients must also be adequately sedated in order to avoid potential injury caused by fighting against the restraints.

Rapid-acting benzodiazepines are often used as first line therapy to treat agitation and prevent seizures (Grade III recommendation). Benzodiazepines have the advantage of being a nonspecific means of controlling agitation when the diagnosis is unclear. While benzodiazepines may be effective in controlling agitation, they do not reverse

delirium. Adverse effects include over-sedation, aspiration, and potential delay in recovery to baseline mental status when compared with the administration of physostigmine, as addressed below [78].

Although intact Jimson weed seeds have been found in vomitus and gastric lavage fluid for many hours after ingestion [28, 85], gastric lavage is difficult, can increase agitation, and is associated with several life-threatening complications such as aspiration pneumonitis, aspiration pneumonia, and esophageal or gastric perforation [86]. It does not shorten the length of ICU stay, overall length of hospitalization, or otherwise improve outcome [85, 87]. Administration of activated charcoal carries the risk of emesis, aspiration, and corneal abrasion [88]. These modalities are contraindicated in patients with altered mental status unless the airway is protected and, generally, are not indicated in the management of anticholinergic plant poisoning.

Physostigmine is a naturally occurring carbamate compound that acts as a short acting acetylcholinesterase inhibitor. It is a specific antidote for anticholinergic toxicity. Physostigmine acts by increasing the concentration of acetylcholine at muscarinic and nicotinic receptors by reversibly inhibiting acetylcholinesterase at the synaptic cleft and neuroeffector junctions [53, 89]. In contrast to other carbamate cholinesterase inhibitors, it is a tertiary amine and crosses the blood-brain barrier, reversing the central as well as peripheral effects of cholinergic blockade. Published guidelines recommend that physostigmine be stocked by facilities that accept emergency patients and be immediately available for the treatment of anticholinergic toxicity [90].

Although a subject of controversy in the past [91–94], physostigmine is considered indicated as an initial treatment to reverse agitation and delirium caused by anticholinergic toxicants, including anticholinergic plants [53, 78, 89, 94, 95] (Grade II-3 recommendation). In a retrospective comparison of therapy with physostigmine versus benzodiazepines in anticholinergic toxicity, physostigmine controlled agitation in 96% of cases (versus only 24% with benzodiazepines) and reversed delirium in 87% of patients (versus no

reversal with benzodiazepines). Side effects of physostigmine were limited to diaphoresis, vomiting, diarrhea, and asymptomatic sinus bradycardia to a rate of 51 beats per minute in one case [78]. In ambiguous cases, physostigmine administration can be used as an aid in diagnosis [40, 89].

Prior cautions against the use of physostigmine were based on reports of dysrhythmias, asystole, and seizures that were temporally associated with its administration, typically in the setting of cyclic antidepressant toxicity [92, 96–98]. Levy reported a case of atrial fibrillation and non-sustained ventricular tachycardia that occurred 45 min after a 2 mg dose of physostigmine in the treatment of anticholinergic symptoms due to Jimson weed seed ingestion [99]. Given the length of the interval between the administration of physostigmine and the reported dysrhythmia, a cause-and-effect relationship seems unlikely. Physostigmine was effective and complications were not reported in several other case reports of anticholinergic plant poisoning and case series that included patients with anticholinergic plant poisoning [2, 15, 24–26, 29, 52, 54, 74, 75, 97, 100–102]. Nevertheless, physostigmine should be used with appropriate caution and administered in a monitored, critical care setting such as an intensive care unit or a monitored area of an emergency department. A reasonable indication for the use of physostigmine is for cases who are not adequately managed with low doses of benzodiazepines. Physostigmine is contraindicated in the presence of severe or clinically active asthma, gangrene, mechanical obstruction of the intestine or urogenital tract, or any significantly vagotonic state. Cholinergic signs may be observed, and bradycardia and seizure can be seen if physostigmine is administered too quickly [103].

Physostigmine is available as physostigmine salicylate in 2 mg ampules, the concentration is 1 mg/mL [103]. In adults, an initial dose of 0.5–1 mg slow IV push with a minimum delay of 10–15 min before re-dosing has been recommended (in children 0.01–0.02 mg/kg) [104]. Physostigmine should be given slowly at a rate of no more than 1 mg per minute in adults and 0.5 mg per minute in children [103]. The half-life

of physostigmine is 18–36 min [105] and the duration of action is about 45–60 min [103]. Anticholinergic effects frequently reemerge after the effects of a physostigmine bolus wanes. Continuous infusion of physostigmine was described in a published case of prolonged and recurrent anticholinergic delirium due to a mixed-drug overdose [106].

Patients who have ingested anticholinergic plants; who present with agitation, delirium, seizure, or hyperthermia; and who receive physostigmine require either ICU care or a prolonged stay in the emergency department for intensive monitoring for worsening anticholinergic toxicity and its consequences and to observe for adverse effects of treatment.

Indications for ICU Admission in Anticholinergic Plant Poisoning

Delirium unresponsive to benzodiazepines and physostigmine
Hallucinations
Repeated doses of physostigmine required to control delirium
Respiratory failure
Airway compromise
Seizures or symptomatic dysrhythmias (both rare)

Criteria for ICU Discharge in Anticholinergic Plant Poisoning

Resolution of delirium and hallucinations
No physostigmine or sedatives required for at least 4–6 h
Resolution of associated respiratory or renal failure

Key Points in Anticholinergic Plant Poisoning

1. Anticholinergic plants are used as hallucinogens.
2. Anticholinergic plants may be mistaken for edible berries or foods.

3. Delirium, hallucinations, tachycardia, dry mouth, and mydriasis are the most common clinical effects.
4. Seizures, rhabdomyolysis, respiratory failure, and renal failure are potential serious complications.
5. There is no routinely available diagnostic test to confirm the diagnosis; however, resolution of delirium after administration of physostigmine is virtually diagnostic of anticholinergic toxicity.
6. Physostigmine is specific therapy for anticholinergic plant toxicity.

When Withering wrote his classic *An Account of the Foxglove and Some of Its Medicinal Uses* in 1785 [1], he recognized the beneficial uses of foxglove (*Digitalis purpurea*); but in the section “Effects, Rules and Cautions,” he described what is now the well-known toxicity of digitalis: “occasions sickness, vomiting, purging, giddiness, confused vision, objects appearing green or yellow; increased secretion of urine, with frequent motions to part with it, and sometimes inability to retain it; slow pulse, even as slow as 35 in a minute, cold sweats, convulsions, syncope, death.”

Intoxication from cardiotoxic plants may result from direct ingestion of plant parts, such as leaves, flowers, nectars, seeds, or roots, or may result from teas (decoctions and infusions) brewed from the plant. In some cases, toxicity has occurred from drinking water from a vase that contained the cut flowers of foxglove or lily of the valley or, according to common folklore, from roasting hot dogs on a branch from oleander [2]. Herbal products, especially those contained in traditional medicines, may contain cardiac glycosides [3–5] or alkaloids from *Aconitum* spp. [6, 7]. Cardiotoxic alkaloid-containing toxic honey was implicated in poisonings in 400 BC. Xenophon reported the poisoning of Greek soldiers by honey made by bees from the nectar of wild rhododendron [8].

Type and Activity of Plant Toxin

Plants producing cardiac toxins may be separated into characteristic groups based on the type and the activity of the plant toxin. These groups include (1) digitalis and digitalis-related compounds, (2) aconitine and related alkaloids, (3) grayanotoxins, and (4) *Veratrum* alkaloids. Table 1 lists common plants and the nature of their cardiotoxic components [2, 9–14].

Digitalis and Digitalis-Like Glycosides

Digitalis, digoxin, and related cardiac glycosides are found naturally in several plant species around the world (see Table 1) [15]. Medicinally important glycosides are obtained from the foxglove

plant. Other plants, such as oleander, lily of the valley, Christmas rose, and sea onion, also contain potentially toxic cardiac glycosides.

Foxglove (*Digitalis* spp.) is a biennial plant commonly grown in North American gardens, but it originates from Southern Europe and Central Asia. During the first year of growth, the plant produces a basal rosette of large oval leaves. In the second year, flowers are borne on a large stalk that matures from the bottom to the top. Each flower is cup shaped with darker spots on the lower inside of the tubular-shaped flower. Blooms vary in color from dark pink or purple (*Digitalis purpurea*) to yellowish or whitish (*Digitalis lanata*). The entire plant is toxic, and poisoning has resulted from consumption of teas brewed from foxglove leaves [16, 17]. In some cases, the leaves during the first-year growth were mistaken for comfrey (*Symphytum officinale*) [2].

Oleander is native to tropical and subtropical climates and comprises two related plants, *Nerium oleander* and *Cascabela thevetia*. *N. oleander* is a tall evergreen shrub frequently grown indoors as an ornamental plant in temperate North America, but it also can be grown outdoors, where it may reach heights of 25 ft. The dark, leathery leaves are arranged in whorls of three, and the flowers, borne in clusters with five petals each, are usually pink, peach, red, or white. Yellow oleander (*C. thevetia*) is similar in shape, with yellow or orange flowers, and produces black fruits with a central stone (seeds). Oleander is particularly enticing to small children because of its lovely flowers and seed pods that are easily accessible [18]. All parts of the plant are toxic; reported cases of toxicity include consumption of oleander leaves [19] or oleander tea derived from the leaves [20] and the ingestion of seeds. In some countries (e.g., Sri Lanka), the ingestion of the seeds of yellow oleander is a common means of suicide [21].

Sea mango (*Cerbera manghas*) is a small tree in the Apocynaceae family found along the coasts of South Asia and Southeast Asia, Polynesia, and Northern Australia. It has been reported as an agent in self-poisonings in Sri Lanka [22] and in Taiwan [14].

Lily of the valley (*Convallaria majalis*) is a small perennial plant with two elliptical, pointed leaves and flowers borne on a single, small stalk. Blooms

Table 1 Cardiotoxic plants

Class	Common name	Scientific name	Toxin
Cardiac glycosides	Purple foxglove	<i>Digitalis purpurea</i>	Digitoxin
	Grecian foxglove; wooly foxglove	<i>Digitalis lanata</i>	Digitoxin, digoxin
	Oleander	<i>Nerium oleander</i>	Oleandrin
	Yellow oleander; be still tree	<i>Cascabela thevetia</i> (<i>Thevetia peruviana</i> , <i>T. neriifolia</i>)	Thevetin A and B
	Christmas rose	<i>Helleborus niger</i>	Helleborin, helleborein
	Lily of the valley	<i>Convallaria majalis</i>	Convallotoxin, convallarin, convallamarin
	Squill or sea onion Sea mango	<i>Urginea maritima</i> <i>Cerbera manghas</i> <i>Cerbera venenifera</i> <i>Cerbera odollam</i>	Scillaren, scillarenin Cerberin
Aconitum alkaloids	Monkshood; wolfsbane	<i>Aconitum</i> spp. (<i>A. napellus</i>)	Aconitine alkaloids
	Larkspur	<i>Delphinium</i> spp.	Delphinine
Grayanotoxins	Rhododendron, azalea	<i>Rhododendron</i> spp.	Grayanotoxin 1 or andromedotoxin
	Japanese pieris; lily of the valley bush	<i>Pieris japonica</i>	Grayanotoxin 1 or andromedotoxin
	Mountain-laurel	<i>Kalmia latifolia</i> ; other <i>Kalmia</i> spp.	Andromedotoxin
<i>Veratrum</i> alkaloids	Indian hellebore; American white hellebore; false hellebore; green hellebore	<i>Veratrum viride</i>	Germidine, germitrine, veratridine, veratrosine, veratramine
	Corn lily	<i>Veratrum californicum</i>	
	Death camas; black snakeroot	<i>Zigadenus venenosus</i>	Zygacine, zygadenine, protoveratrine

are small, cup shaped, white, and fragrant and are located along only one side of the flower stem. Bright red berries form later in the season along the flower stalks. Lily of the valley is reported by the Poisons Information Centre as a common plant exposure for children in Helsinki [23], and accidental ingestion has resulted in intoxication [24, 25].

Hellebore, or Christmas rose (*Helleborus niger*), is an herbaceous perennial from the buttercup family, with compound leaves and white or sometimes purplish flowers that bloom in the spring or winter. Although the plant contains cardiac glycosides, reported poisonings are rare [2]. This plant should not be confused with the *Veratrum* spp., which sometimes are called *false hellebore* (see later).

Squill (*Urginea maritima*) or sea onion is a perennial plant with lilylike leaves and small white flowers borne off terminal clusters.

Ingestion of the bulbs has produced effects consistent with cardiac glycoside toxicity [26].

Aconitum and Related Alkaloids

Monkshood, aconite, or wolfsbane (*Aconitum* spp., e.g., *Aconitum napellus*), a perennial plant originally native to Europe, is found within North America. The plant grows 3–4 ft tall from a tuberous root and has deeply divided palmate leaves. The flowers are borne off a long spike, each flower containing five petaloid sepals, with one shaped in the form of a monk's hood. Blooms vary in color, including purple, blue, and combination of purple and white. Related species are grown in China and Japan. *Aconitum carmichaelii* and *Aconitum kusnezoffii* are the main source of medicinal aconite drugs, *ts'ao wu* (*wu t'ou*) and *fu tzu* (*ch'uan wu*) [10, 27].

Delphinium and larkspur (*Delphinium* spp.) are perennial, biennial, or annual plants similar in appearance to monkshood with deeply divided leaves; various species grow from 6 in. to 6 ft tall. The flowers are usually borne off multiple racemes or flower clusters, each flower, commonly blue, containing a long “spur” off the back, hence the name *larkspur*.

Aconitine and delphinium alkaloids are under investigation as potential analgesic and anti-inflammatory drugs [28–30], and *Aconitum* roots currently are used in preparations of Chinese and Japanese medicines for the treatment of rheumatic and neurologic diseases [31, 32]. This usage frequently results in unintentional, potentially fatal, toxicity [6, 7, 31–36].

Grayanotoxins

Rhododendrons (*Rhododendron* spp.) are large evergreen shrubs with leathery leaves and large, showy flower clusters, each flower containing protruding stamens. Bloom colors are highly variable, depending on the hybrid, but can be pink, purple, maroon, or red. The related azaleas are either evergreen or deciduous small shrubs, with additional flower colors of white, orange, salmon, or crimson. Japanese pieris (*Pieris japonica*), also known as the *lily of the valley bush*, is an evergreen with dark, leathery leaves, bearing chains of white, urn-shaped flowers in the spring. Although native to Japan, this small shrub is found frequently in gardens of North America. Mountain-laurel, *Kalmia latifolia*, and other *Kalmia* spp. are small, evergreen shrubs that produce clusters of white to pinkish, bell-shaped flowers.

Toxic diterpenoids (grayanotoxins, also known as andromedotoxins, rhodotoxins, or acetylandromedol), mainly grayanotoxin I or andromedotoxin, are responsible for poisonings attributed to toxic honey, which is produced by bees collecting pollen from *Rhododendron* spp. [37, 38]. Toxic honey, known in Turkey as *deli bal* or *tutan bal*, is ingested as a treatment for gastritis and peptic ulcers [8]. Sucking azalea nectar from the flower may pose less of a hazard [39].

Veratrum Alkaloids

Indian hellebore, also called *American white hellebore*, *false hellebore*, or *green hellebore* (*Veratrum viride*), is an herbaceous perennial with oval, alternately arranged leaves. Each leaf has prominent parallel veins, and the flowers, borne in terminal clusters, are greenish white. Related species, such as *Veratrum californicum* (or corn lily), have white flowers [2]. Confusion of *Veratrum* spp. with other plants, particularly gentian, has led to ingestion of the plant or of wine made from *Veratrum album* [40–43]. Death camas (black snakeroot, *Zigadenus venenosus*, and other species) is a perennial plant in the lily family with grasslike leaves grown from a bulb. Creamy white flowers are clustered together and borne off a single central stalk. Toxicity arises from ingestion of the bulbs [44], frequently mistaken for wild onion [45].

Biochemistry of Cardiotoxic Substances in Plants

Plant Cardiac Glycosides

The plant cardiac glycosides, known as *cardenolides*, have a characteristic chemical structure consisting of an aglycone or genin (i.e., a steroid nucleus joined to a lactone ring) attached to one to four sugar moieties (Fig. 1). The aglycone is essential for the pharmacologic activity of the glycoside, whereas the sugar moieties, specific for each cardenolide, affect the water and lipid solubility and the potency [18, 46].

The foxglove plant produces several cardiac glycosides, most notably digoxin from the Grecian foxglove (*D. lanata*) and digitoxin from the purple foxglove (*D. purpurea*) and from *D. lanata* [12].

D. lanata contains the precursor glycosides, lanatosides A, B, and C. After mild alkaline hydrolysis to remove an acetyl group and enzymatic hydrolysis to remove glucose, digitoxin and digoxin are produced from lanatosides A and

Fig. 1 Chemical structures of plant glycosides, including major component divisions

Fig. 2 Chemical structure of aconitine

C. D. purpurea contains the precursor purpurea glycoside A, which contains no acetyl groups, and enzymatic hydrolysis is sufficient to produce digoxin [12]. Because digitoxin is less polar than digoxin, it avidly binds to serum albumin, which results in a longer distribution phase than digoxin [12].

Oleandrin and thevetin A have a structure similar to digitoxin but with varying sugar residues attached at the number three carbon of the "A" ring on the steroid nucleus [18]. The genins for thevetin B and digitoxin are identical, with the only difference being that in thevetin B a thevetose and gentiobiose are conjugated to oxygen at the number three carbon [47]. Oleandrin and, to a lesser extent, oleandrogenin bind to albumin [48].

Latex from *C. manghas* contains cardenolides such as cerberin, neriifolin, and cerebroside.

Aconitine and Related Cardiotoxic Alkaloids

Compounds derived from *Aconitum* spp. (principally the tubers or root stock) are diterpenoid alkaloids (i.e., a nitrogenous base formed from some C₂₀-terpenoid precursors) (Fig. 2) [31]. The most toxic alkaloids are aconitine, mesaconitine, and 3-acetylaconitine. The presence of a benzoylester side chain at carbon 14 produces the arrhythmic effects attributed to these three alkaloids [31]. The alkaloids contained within the plant vary depending on the species and the geographic location, with some species being more toxic than others [49]. Raw tubers are "processed" by boiling or steaming *bushi* under high pressure in Japan and China to produce *kako-bushi*. This process reduces the toxicity of the parent alkaloids by producing less toxic pyro-type aconitine alkaloids [50].

Grayanotoxins

Grayanotoxins are diterpenoids with a perhydroazulene skeleton [51] found primarily in the leaves of shrubs in the heather family (e.g., rhododendrons, azaleas, and mountain-laurel). Grayanotoxins I, II, and III differ by virtue of (1) a hydroxyl group off carbon 10 in grayanotoxins I and III, which is a carbonyl in grayanotoxin II, and (2) a hydroxyl moiety at carbon 14 in grayanotoxins II and III, which is esterified to an acetyl in grayanotoxin I (Fig. 3). The content of grayanotoxin I in a fresh leaf from *Rhododendron ponticum* was estimated at 0.024% [52].

Veratrum Alkaloids

Veratrum alkaloids are steroid-like, polycyclic, nitrogen-containing structures [11]. Veratrine is a mixture of alkaloids, with veratridine being one of the major components. All *Veratrum* alkaloids are based on a steroid nucleus, with a fused two-ring, *N*-containing heterocycle added across the 13–17 bonds (Fig. 4). Protonation of this nitrogen makes these drugs primarily cationic at physiologic pH. The steroid 3-position oxygen exists as a hydroxyl, in weakly active cevine, esterified to veratric acid in moderately potent veratridine and to methyl-butenoic acid in the highly potent cevadine. The 6–7 hydroxyl groups on these molecules account for their (limited) aqueous solubility, whereas differences in potency result primarily from varied substituents at the 3-hydroxyl position.

Grayanotoxin I: R₁ = OH; R₂ = CH₃; R₃ = COCH₃

Grayanotoxin II: R₁R₂ = H₂C=; R₃ = H

Grayanotoxin III: R₁ = OH; R₂ = CH₃; R₃ = H

Fig. 3 Chemical structures of grayanotoxins

Pathophysiology

Plant Digitalis Glycosides

Digitalis compounds exert a positive inotropic effect on the heart and have arrhythmogenic activity. Cardioactive steroids are specific inhibitors of the membrane protein sodium pump (Na⁺,K⁺-ATPase) [53]. Na⁺,K⁺-ATPase effectively moves ions across membranes and maintains transmembrane Na⁺ and K⁺ gradients with energy generated from the hydrolysis of adenosine triphosphate (ATP). The enzyme is composed of three subunits (α, β, and γ), with the α subunit containing the Na⁺,K⁺, and ATP-binding sites and the binding site for cardiac glycosides [53]. Inhibition of the pump by cardiac glycosides reduces active Na⁺ efflux, resulting in increased intracellular [Na⁺] and effectively lowering the Na⁺ gradient-dependent driving force that powers plasmalemmal sodium-calcium exchange. The net effect is an increased intracellular calcium concentration, leading to an elevated amount of calcium released during cardiac systole and increased force development, the positive inotropic effect (Fig. 5). By a totally different mechanism, these cardiotoxic steroids are thought to modify the ion selectivity of the voltage-gated Na⁺ channel to a state of “promiscuous permeability” or “slip-mode conductance” (meaning calcium follows sodium), allowing the usually impermeant Ca²⁺ to enter cells through Na⁺ channels. This Ca²⁺ influx promotes Ca²⁺ release from the sarcoplasmic reticulum [54]. The steroidal alkaloid veratridine also increases the calcium conductance of voltage-gated Na⁺ channels, suggesting the possibility of a generalized action of steroid-containing drugs on this ion channel. The positive inotropic effect of cardiac glycosides results from the increases in intracellular calcium effected by both of these mechanisms since more calcium is now available for the myocardial contractile elements.

With toxicity, cardiac glycosides can cause many possible arrhythmias (see ► Chap. 38, “Digitalis Glycosides”). Junctional pacemakers can discharge at an increased rate, leading to nonparoxysmal atrio-ventricular junctional tachycardia [53]. Enhanced

Fig. 4 Chemical structures of *Veratrum* alkaloids

Fig. 5 Membrane ion flux of Na^+ and Ca^{2+} in the heart. Glycoside-induced inhibition of Na^+, K^+ -ATPase secondarily inhibits the Na^+ influx- Ca^{2+} efflux exchange reaction (From Ref. [96], p. 217)

automaticity and impaired conduction, such as an atrioventricular block with an accelerated junctional pacemaker, are consistent with digitalis toxicity. Sinus bradycardia, sinoatrial arrest, and heart block (second-degree or third-degree atrioventricular block) also are associated with toxicity. Oleandrin, the major cardiac glycoside found in oleander, also functions as a Na^+, K^+ -ATPase pump inhibitor and produces pathophysiologic changes similar to those of digoxin overdose (see ► Chap. 38, “Digitalis Glycosides”). As with digitalis, severe poisoning produces conduction defects in the sinus node (sinus bradycardia, sinus arrest, or exit block), atrioventricular node (second-degree or third-degree heart block), or both. Higher serum cardiac glycoside levels correlate with involvement of both nodes [55]. There may be decreased atrioventricular conduction and bradycardia secondary to increased vagal tone resulting from increased carotid sinus baroreceptor firing in response to sodium/calcium influx and increased vagal outflow. Acute cardiac glycoside toxicity produces systemic hyperkalemia secondary to Na^+, K^+ -ATPase pump inhibition, with a shift of potassium extracellularly from all tissues in the body (e.g., release from skeletal muscle). Cardenolides from *Cerbera* species (cerberin,

neriifolin, and cerebroside) also cause cardiac dysrhythmias and hyperkalemia due to inhibition of the Na^+/K^+ ATPase [22].

Aconitine, Grayanotoxins, and Veratridine

Although digitalis and digitalis-like compounds primarily inhibit the Na^+/K^+ -ATPase pump, aconitine, grayanotoxins, and veratridine are “activator” agents that open sodium channels [56]. The cardiac conduction tissues and the autonomic nerves innervating the heart are affected by these activators; both actions contribute to the clinical presentation. Aconitine and veratridine bind within the transmembrane region, known as *neurotoxin receptor site 2* [57]. This binding produces persistent activation of the voltage-gated Na^+ channel (Fig. 6) at the resting membrane potential and concomitant inhibition of channel inactivation. A persistent Na^+ permeability, a relatively constant inward current, and depolarization of the excitable cardiac membrane result. Persistent channel opening also produces prolonged phase 3 depolarization in cardiac

myocytes, inducing afterpotentials with generated automaticity.

Similarly, grayanotoxin I and α -dihydrograyanotoxin and *Veratrum* alkaloids (veratrine with a steroidal skeleton, jervine, veratramine, or those with a cevanine skeleton, protoveratrine A, protoveratrine B, veratridine) increase the resting sodium permeability by holding transmembrane sodium channels open at rest [51]. As a result of this permeability increase, the resting membrane depolarizes, resulting in spontaneous action potentials that produce neurotransmitter release and cardiac dysrhythmias. This persistent, toxin-modified sodium permeability, if present in cardiac membranes, results in prolonged atrial and ventricular action potentials, often followed by oscillatory afterpotentials [58]. If enough of the sodium channels are bound by toxin, the resulting depolarization is so large that the remaining toxin-free channels become inactivated, and the membrane becomes refractory, preventing further conduction.

Specific diterpenoid alkaloids from *Aconitum* and *Delphinium* spp. most likely cause hypotension and bradycardia through activation of autonomic reflexes [59]. This activation produces an end result at the level of the carotid sinus similar to

Fig. 6 Postulated conformational arrangements of cardiac Na^+ channels compatible with the concept of resting, activated, and inactivated states. Transitions between resting, activated, and inactivated states depend on membrane

potential and time. Aconitine, veratridine, and related toxins maintain the channel in the activated state. Potentials for each state are shown under each channel schema as a function of time (From Ref. [96], p. 198)

that of digoxin: reflex stimulation of vagal tone manifested chiefly as decreased heart rate and atrioventricular block. *Veratrum* intoxication also produces vagal reflex hypotension and bradycardia through a similar mechanism, most likely secondary to withdrawal of peripheral α -adrenergic tone [60]. Neuronal responses to systemic activator alkaloids include a range of positive and negative symptoms as nerves that are “weakly affected” show spontaneous repetitive firing and exaggerated transmitter release, whereas “strongly affected” nerves show depolarizing block. Perioral innervation manifests both effects, with paresthesia (positive) and numbness (negative) occurring simultaneously in the lips and tongue. Aconitine also is thought to have other ion (e.g., K^+) channel effects that produce a prolonged QT interval and possibly torsade de pointes [36].

Clinical Presentation and Life-Threatening Complications

Plant Cardiac Glycosides

Manifestations of oleander poisoning are the same as those of digitalis glycosides poisoning (see ► Chap. 38, “Digitalis Glycosides”), although differences in bioavailability of the plant-derived glycosides make the clinical course less predictable. Early after an overdose, oleander poisoning causes nausea, vomiting, decreased appetite, and diarrhea, as well as weakness and dehydration. Patients may have changes in consciousness, with lethargy progressing to confusion and coma. Seizures also have been described after oleander ingestion [61]. Visual disturbances and yellow-green vision may occur [20, 62].

Cardiac dysrhythmias and conduction disturbances may supervene at any time; bradydysrhythmias and tachydysrhythmias may be seen [5, 61, 63]. Bradycardia may be more common; in one review of 170 cases of yellow oleander poisoning, atrioventricular block was seen in 52.4% of patients, and bradycardia was seen in 49.5% [64]. Atrioventricular block or complete dissociation may produce complex junctional or reentrant dysrhythmias [62, 63, 65], which may

degenerate into life-threatening ventricular tachycardia or fibrillation or sudden cardiac arrest [20]. Electrolyte disturbances, related to paralysis of the cellular Na^+, K^+ -ATPase pump, are manifest as hyperkalemia with peaked T waves on electrocardiogram (Fig. 7).

Aconitine and Related Cardioactive Plant Alkaloids

Aconite is one of the most potent plant-derived toxins known, with severe poisoning caused by 5 mL of the tincture, 0.2 mg of aconitine, or 1 g of the cured plant [66]. Aconitine has systemic toxicity, with gastrointestinal disturbances present within hours after poisoning, including the early onset of nausea, hypersalivation, and vomiting. Neurotoxicity may include numbness, ataxia, dysarthria, perioral paresthesias, weakness of the extremities, and deteriorating consciousness leading to seizures and coma [34].

Characteristic bradydysrhythmias and hypotension support the diagnosis. Ventricular ectopy can be life-threatening, with ventricular tachycardia or fibrillation or both preceding asystole. Cardiac conduction disturbances include QRS widening, a prolonged QT interval, and bundle branch block. Toxicity progresses rapidly, with life-threatening cardiotoxicity evident often within 2 h of the ingestion. Death results from direct myocardial depression and cardiovascular collapse or from a malignant dysrhythmia [34, 35].

Metabolic disturbances, such as metabolic acidosis, hypokalemia, and hyperglycemia, are sometimes seen [35]. In addition, serum creatine kinase may also be elevated [35].

Grayanotoxins

Grayanotoxins cause dose-dependent manifestations that are similar to the manifestations associated with poisoning by *Veratrum* alkaloids. Grayanotoxin poisoning from mad honey ingestion has been associated with sudden onset of vomiting, chest pain, nonspecific ST elevation, and bradycardia, mimicking an acute myocardial

Fig. 7 ECG tracing in an adult woman who ingested yellow oleander and suffered AV conduction abnormalities and dropped beats typical of digitalis-related compounds (Courtesy of Dr. Raja Selvaraj)

infarction [67]. In one report of 23 victims of grayanotoxin-contaminated honey in Turkey, the most common clinical effects included hypotension, bradycardia, nausea, and vomiting. Sweating, faintness, weakness, dizziness, chills, exhaustion, impaired consciousness, and blurred vision also were common [68]. Victims of massive overdoses may develop seizures, severe cardiac conduction delays, and life-threatening ventricular ectopy [38]. Complete (third-degree) atrioventricular block has been documented in a case of mad honey intoxication [69]. In another case, atrial fibrillation with slow ventricular response was observed [70]. Grayanotoxins are rapidly metabolized and excreted [71]. Patients who are supported through the severe gastrointestinal and cardiovascular toxicity usually survive and become symptom-free 1–5 days later [8, 69, 70].

sweating, dilated pupils, blurred vision, respiratory depression, light-headedness, headache, and syncope are reported commonly by victims [41]. Myalgias, weakness, muscle spasms, paresthesias, and myoclonus have been reported [42]. Cardiovascular effects include hypertension or hypotension, bradycardia, and sinoatrial or atrioventricular blocks. Ventricular dysrhythmias may occur with massive overdoses [41, 42]. In one case series of four patients, who mistook white hellebore for wild garlic while foraging, symptoms included nausea and vomiting, confusion and dizziness, hypotension, and bradycardia; one patient had inverted T waves and transient blindness. All survived, becoming symptom-free within 24 h [72].

Diagnosis

Laboratory Detection of Plant Toxins

Veratrum Alkaloids

Poisoning by the glycoalkaloids from ingestion of hellebore causes symptoms within 30–60 min of the exposure. Nausea and repeated vomiting with intense abdominal pain and sometimes diarrhea herald the onset of toxicity. Paresthesias, salivation,

Detection of cardiac glycosides from plants is viable with existing analytical methodologies. Clinical laboratories capable of performing immunoassay procedures can detect digitalis compounds because they cross-react with assays used for therapeutic drug monitoring. Detection of

oleandrin in serum using digoxin immunoassays has been reported using various technologies FPIA (fluorescence polarization immunoassay), MEIA (microparticle enzyme immunoassay), and two turbidometric immunoassays. However, a chemiluminescent assay (Bayer Diagnostics, now a part of Siemens Diagnostics) showed no cross-reactivity [73–76]. While FPIA methodologies showed the highest cross-reactivity with oleandrin, Abbott Laboratories have discontinued the assays. Alternative assays are available, and, for example, the Dimension Vista digoxin assay (Flex Reagent Cartridge, Siemens Diagnostics, Deerfield, IL) can detect oleandrin comparable to FPIA assays. EMIT assays are also capable of detecting oleandrin [77]. However, since immunoassay methodologies vary in their ability to detect cardiac glycosides, they should be used for a qualitative assessment of exposure rather than for quantitative purposes.

Squill ingestion has produced apparent serum “digoxin” levels of 1.59 ng/mL by enzyme immunoassay [26]. Similarly, convallatoxin from lily of the valley has been identified through digoxin immunoassays that cross-react. Cross-reactivity was tested using several assays and analyzers: two different chemiluminescent assays, one on the Siemens Immulite 2000 analyzer and one using a microparticle immunoassay on the ci8200 Abbott Architect analyzer; an Elecsys electrochemiluminescence immunoassay on a Roche Cobas e601 analyzer; a latex agglutination assay on the Roche Cobas c501 analyzer; and MEIA on the Abbott AxSYM analyzer [78]. Cross-reactivity was variable, but the Abbott Architect showed the highest sensitivity for detecting convallatoxin.

However, specific identification of cardiac glycosides, such as digoxin, digitoxin, deslanoside, digoxigenin, and digitoxigenin, may require sophisticated applications, such as high-performance liquid chromatography-tandem mass spectrometry (HPLC-MS) [79] or HPLC-ion-spray-mass spectrometry [80]. Similarly, oleandrin has been assayed in cases of oleander poisoning using HPLC [81] or HPLC-MS with serum concentrations of 1.1 ng/mL [82]. For medico-legal investigations, detection of oleandrin

should be confirmed by tandem mass spectrometry or other more sophisticated methodologies such as liquid chromatography-three-dimensional quadrupole mass spectrometry equipped with sonic-spray ionization [83]. Specimens are also stable in serum-separated tubes and therefore can be sent to reference laboratories for further analysis without concern for a decline in toxin concentration [84]. Chromatographic methods have been used to detect grayanotoxins (andromedotoxins) in material obtained from the rumen contents of poisoned sheep and goats [52] and in honey responsible for poisoning humans [8]. There is interest in developing a quantitative grayanotoxin assay that can correlate blood or urine concentrations with the clinical severity of “mad honey poisoning” [85]. Similarly, thin-layer chromatography and ionization spectrometry have been used to detect *Veratrum* alkaloids in wine produced from *V. album* [43]. Detection of aconitine in the blood, serum, and plasma is most helpful if poisoning is suspected. Applications using various chromatographic techniques, particularly liquid chromatography, in conjunction with mass spectrometry, have been used [86, 87]. Although these methods may confirm the presence of one of these toxins, they are unavailable in most clinical laboratories.

Treatment

Resuscitation and Supportive Care

Patients with life-threatening poisoning from plant cardiotoxins may require advanced cardiac life support. The initial approach should be carried out according to current algorithms established for cardiopulmonary resuscitation (CPR) and emergency cardiovascular care (ECC) by the American Heart Association [88].

Decontamination

If the patient presents to medical care having ingested a cardiotoxic plant, he or she might benefit from gastrointestinal decontamination with activated charcoal in an attempt to reduce

absorption of cardiotoxins. Activated charcoal is the preferred agent because it should effectively adsorb cardiac glycosides, aconitine, veratrine, and other active toxicants while they are still in the stomach. Studies have confirmed the ability of charcoal to bind oleandrin [89–91]. However, the administration of activated charcoal has not been documented to be of benefit in these patients [90]. Also giving charcoal by mouth to a drowsy patient with an unprotected airway risks pulmonary aspiration, which can be a life-threatening complication. The ► [Chap. 14, “The Assessment and Management of Hypotension and Shock in the Poisoned Patient”](#) provides greater detail on the administration of activated charcoal. Multiple-dose activated charcoal was found to be safe and of some benefit in one randomized controlled trial in the treatment of patients suffering yellow oleander poisoning (level of evidence [LoE] I) [92].

Indications for ICU Admission in Plant-Derived Cardiac Glycoside Poisoning

History of massive overdose and early onset of clinical effects
 History of overdose and unusually susceptible patient (e.g., extremes of age, underlying congenital or acquired cardiac disease)
 Life-threatening cardiac rhythm disturbances (or potentially life-threatening with evidence of progression)
 Life-threatening cardiac conduction disturbances or asystole
 Life-threatening hemodynamic instability
 Severe metabolic disturbances (e.g., hyperkalemia)
 Progressive deterioration in level of consciousness
 Seizures or coma

Extracorporeal Removal Techniques

Patients are unlikely to derive any benefit from hemodialysis in cardiotoxic plant poisoning, given the large molecular size of these alkaloids

and other natural compounds. The value of hemoperfusion has not been established.

Specific Treatments

Cardioversion or transcutaneous cardiac pacing may be lifesaving for patients with cardiac toxicity from plants (LoE III). In the series by Eddleston and associates of 66 patients with yellow oleander poisoning, six patients (10%) required a temporary pacemaker [65].

Antidysrhythmic agents have been suggested for malignant arrhythmias associated with aconite poisoning but with mixed success [5]. Successful management of hyperkalemia also may resolve cardiac conduction disturbances (LoE III).

Vasopressors, such as norepinephrine, may be needed in addition to intravenous fluids to treat refractory hypotension. Standard anticonvulsants, such as benzodiazepines, are a rational choice of treatment for aconite-associated seizures.

Antidotes

Digoxin Fab-specific antibodies have been used successfully to treat patients with significant poisoning by oleander or other cardiac glycoside-containing plants (LoE I) [65, 93, 94]. In a randomized controlled trial, Eddleston and associates [65] showed that Fab fragments resolved dysrhythmias and bradycardia after yellow oleander poisoning rapidly, often within 2 h of administration. These authors note that the relatively short half-life of Fab fragments (16 h) and continued absorption of cardiac glycosides from ingested oleander seeds may account for recrudescence symptoms. The lower affinity of Fab fragments for oleandrin and other natural toxicants than for digoxin may account for recurrent dysrhythmias seen in some patients. In Eddleston’s series, recrudescence of oleander-related bradycardia was noted in three patients 48 h after the initial administration of Fab antibodies [65]. In the context of oleander poisoning, an empirical dose of 800 mg

Table 2 Indications for digoxin immune FAB in plant-derived cardiac glycoside poisoning

For the treatment of life-threatening complications of history-confirmed oleander, foxglove, or other plant-derived cardiac glycoside poisoning:
Severe ventricular arrhythmias (e.g., ventricular tachycardia or fibrillation)
Progressive bradyarrhythmias (e.g., severe sinus bradycardia or second-degree or third-degree heart block not responsive to atropine)
Potassium concentrations >5 mEq/L in the context of severe poisoning

Note: Each vial of Digibind contains 38 mg of digoxin-specific Fab fragments, which bind approximately 0.5 mg of digoxin or digitoxin. Plant-derived cardiac glycosides have lower binding affinities for the Fab, however. Patients poisoned by plant-derived cardiac glycosides may require a substantially increased dose of the antidote over that conventionally used in the treatment of digitalis poisoning, and they may require repeated administration in patients with normal renal function

of Fab fragments may be given as a starting dose. This is a larger dose than is typically used in the initial treatment of pharmaceutical digoxin poisoning and is recommended because of the lower binding affinity of the antibody to the natural cardiac glycosides. Suggested indications for the administration of digoxin immune Fab are listed in Table 2. Although this has not been formally studied, we suggest that the pediatric dose should be similar to that for adults, with appropriate adjustment of total fluid volume.

Of note, a newer digoxin immune Fab, a digoxin-specific antibody (Protherics Inc, Brentwood, Tennessee) approved by the US Food and Drug Administration in 2001, has also been studied for the treatment of chronically digoxin-poisoned patients and appears to be safe and effective [95].

Criteria for ICU Discharge in Plant-Derived Cardiac Glycoside Poisoning
With coma, seizures, or gastrointestinal upset: normalization of consciousness, resolution of gastrointestinal symptoms, and no

evidence of progressive cardiac disturbances after at least 24 h of monitoring
After administration of the antidote: stable heart rate and rhythm for at least an additional 48 h of continuous cardiac monitoring with no evidence of recrudescent cardiac toxicity
After administration of the antidote: resolution of hyperkalemia and associated electrocardiogram findings and on monitoring for at least an additional 48 h, no evidence of rebound hypokalemia or recrudescent hyperkalemia

Special Populations

Pediatric Patients

Because of their smaller size and lower weight, children receive larger weight-based doses of the toxins when they ingest poisonous plants. Because most of the life-threatening clinical effects associated with aconite, *Veratrum* alkaloids, grayanotoxins, and cardiac glycosides are dose dependent, children are theoretically a more vulnerable group. In addition to their smaller size, the oral behaviors, natural curiosity, and developmental immaturity of toddlers place them at a higher risk for inadvertent poisoning by plants.

Elderly Patients

The relative instability of the cardiovascular system of some elderly patients and their diminished capacity to detoxify and eliminate toxins place them at high risk for toxic effects from plants. The elderly already may be on cardiac medications and have underlying cardiac disease, which may compound the adverse effects of poisoning from plant cardiotoxins.

Other Special Populations

Immigrant populations and others who practice herbal medicine constitute a group at higher risk for inadvertent poisoning by cardiotoxic plants.

Key Points in Plant-Derived Cardiac Glycoside Poisoning

1. Cardiotoxic plant poisoning can occur in plant foraging individuals who make mistakes, suicidal patients, those experimenting with herbal tea or alternative therapies, or children.
2. Plant-derived alkaloid toxins may or may not be detected by conventional laboratory assays. Management of symptomatic patients with a history of poisoning should not be delayed.
3. Digoxin Fab antibody administration may be helpful in the management of patients with significant oleander or foxglove poisoning.
4. Multiple and varying cardiac rhythms, with conduction disturbances, ventricular excitability, and ST segment depression, and poor response to atropine and other initial management measures are poor prognostic signs.

Poison hemlock (*Conium maculatum*) is regarded as one of the most poisonous plants worldwide. This plant is a member of the family of Apiaceae (Umbelliferae). The term *Umbelliferae* originates from *umbellula*, which means “little shade,” referring to the parasol-shaped clusters of flowers. Other members of this family include celery (*Apium graveolens*), lovage (*Levisticum officianale*), angelica (*Angelica archangelica*), carrots (*Daucus carota*), and parsnip (*Pastinaca sativa*). Poison hemlock has been misidentified as the aforementioned edible species and consumed, leading to toxic exposure [1]. However, this misidentification occurs infrequently because of the plant’s “mousy” odor, bitter taste, and burning in the mouth after ingestion.

Poison hemlock was the official poison of ancient Greece and was used by executioners during this period [2]. It typically was mixed into a concoction containing conium juice, opium, and other alkaloids. This type of extract is believed to have been administered to Socrates in 399 BC, when he was condemned to death. The ability of the hemlock to induce a motor paralysis was elegantly documented by Socrates’ student Plato, who was at his bedside during his death: “The man who administered the poison kept his hand upon Socrates, and after a little while examined his feet and legs; then pinched his foot hard and asked if he felt it. Socrates said no. Then he did the same to his legs; and moving gradually upwards in this way let us see that he was getting cold and numb [3].”

Fig. 1 Poison hemlock (*Conium maculatum*). (From Graeme KA, Braitberg G, Kunkel DB, et al: Toxic plant ingestions. In Auerbach PS [ed]: Wilderness Medicine, 4th ed. Philadelphia, Mosby, 2001, p 1114, with permission.)

Poison hemlock typically grows to a height of about 2 m. The stem is large and hollow and contains purple spots that are considered an identifying characteristic – hence one of its common names, *spotted hemlock* [1]. Its foliage and leaves are three times divided (tripinnate), similar to a fern (Fig. 1). Poison hemlock develops white flowers that are organized into a flowering head in which the pedicles, individual flower stems, all spring from one point; this is called an *umbel*. Its long, solid white taproot also is characteristic of this species. Poison hemlock can grow anywhere adequate moisture is supplied; it is often found in pastures and meadows and alongside streets and streams. Hemlock can be found throughout the world, although most ingestions occur in North and South America, Europe, western Asia, and Australia. *C. maculatum* is native to Europe and Asia and was introduced to America as an ornamental plant [4]. Poison hemlock growing in the southern climates is thought to be more poisonous than that in temperate regions. Ancient Greeks considered the poison hemlock growing in Macedonia to be the most toxic substance [5].

Toxicity can follow ingestion of any part of the plant, including leaves, stems, roots, flowers, or seeds. Severe toxicity has occurred in children, when the stems were used as whistles [6]. Toxicity is reduced, but not eliminated, when the plant is dried [4]. Toxicity in humans has occurred after consumption of small birds (skylarks, chaffinches, robins) that recently ingested hemlock

buds [7]. Powdered *C. maculatum* has also been reported for sale on the internet [8]. Overall, most exposures are unintentional and dose limited and exposures are more frequent in children.

The active alkaloids in poison hemlock are physiologically and structurally related to nicotine. The syndrome caused is the result of direct effects on nicotinic receptors. Other plants, such as those of the genus *Nicotiana* (which includes tobacco plants), act in a similar fashion.

Poison hemlock has many common names throughout the world, such as *cicuta* (Argentina, Colombia, Chile), *hemlock* (England), *grande cique* (France), *giftjeks* (Norway), *odort* (Sweden), *wild carrot* (Australia), *cigue maculee* (Canada), and *doku-ninjin* (Japan) [8, 9]. Poison hemlock should be distinguished from water hemlock (*Cicuta maculata*).

Biochemistry

The biologic activity of the plant originates from the simple alkaloids found within poison hemlock. Hemlock, similar to other alkaloid containing plants, is bitter tasting. Ten piperidine alkaloids have been identified from *C. maculatum*: λ -coniceine, coniine, *N*-methyl coniine, conhydrine, pseudoconhydrine, conhydrinone, *N*-methyl pseudoconhydrine, 2-methylpiperidine, 2-n-pentyl-3,4,5,6-tetra-hydropyridine, and 5-hydroxy-2-n-pentyl-piperidine [4, 10]. The two principal toxins, λ -coniceine and coniine, are thought to be responsible for both the acute and chronic clinical manifestations of poison hemlock intoxication. These are the two alkaloids found in greatest proportion within the plant and are the focus of the following discussion (Fig. 2) [4]. They are synthesized combining eight two-carbon-acetate units. Reduced nicotinamide-adenine dinucleotide phosphate-dependent λ -coniceine reductase catalyzes the synthesis of coniine [11]. This is a reversible reaction, allowing for the interconversion between the two alkaloids [12]. These substances are structurally similar to nicotine (see Fig. 2), a pyrrolidine alkaloid, and stereospecifically bind to cholinergic ligand-gated sodium channels at nicotinic sites. Similar to nicotine,

Fig. 2 Chemical structures of major alkaloids in poison hemlock. The chemical structure of nicotine is shown for comparison

coniine and related alkaloids have an initial excitatory effect followed by a depressant effect on the central nervous system.

Additionally, twenty-four different steroids have been recently identified in *C. maculatum*. The clinical implications of these compounds have yet to be determined [13].

Coniine and λ -coniceine are present in the plant at varying concentrations and proportions depending on the season, nutrients available, and amount of rainfall. During dry, sunny seasons, the average fruit size and toxin amount increases. During rainy seasons, the λ -coniceine alkaloid predominates [14]. The relative concentrations of these two alkaloids also change as the plant matures [12]. λ -Coniceine is the predominant alkaloid in the leafy parts of poison hemlock and in the early stages of development from flower to fruit [12]. The overall change in λ -coniceine to coniine is associated with rapid growth of the fruit. The peak in λ -coniceine concentration precedes the peak of coniine concentration. As the fruit approaches the final stage of maturation, the coniine content declines, and there is another slight increase in the λ -coniceine concentration [12]. The percentage of total alkaloid weight compared with plant weight varies from 0.009% in dry stems to 0.750% in dry seeds harvested in the midwinter. Fresh secondary growth material is midway between, at 0.075% [15]. Determination of the median lethal dose based on ingested plant weight will vary depending on the season, part of plant ingested, and degree of plant maturation.

Conhydrine, similar to λ -coniceine, is an oxidation product of coniine [14]. Conhydrine

concentrations peak at approximately the same time as λ -coniceine, which is during the rainy season. *N*-methyl coniine, another minor alkaloid, concentrations increase when coniine is at its peak. It is not clear how coniine is converted to *N*-methyl coniine. However, coniine and *N*-methyl coniine predominate in mature seeds [12].

Pathophysiology

Pharmacokinetics of Poison Hemlock

Volume of distribution: 1 L/kg

Protein binding: <5%

Mechanism of clearance: excretion in the kidneys and lungs; metabolized in the liver

Active metabolites: none known

The physiologic effects of coniine are complex and dose dependent. Most toxicity occurs when coniine and related alkaloids enhance the nicotinic actions of acetylcholine by depolarizing voltage-gated nicotinic acetylcholine receptors in the central nervous system, at neuromuscular junctions, postganglionic autonomic nerves, and the adrenal medulla. Muscarinic effects of acetylcholine are typically unaffected. The N_M type nicotinic receptors are found at the skeletal neuromuscular junction, and the N_N variety is found at nerve terminals (Fig. 3). The alkaloids' agonist properties on nicotinic receptors are the predominant mechanism responsible for the clinical effects. Receptor stimulation results in sodium channel influx, leading to membrane depolarization and action potential propagation. Although the effect on the nicotinic receptor-controlled structures is initially stimulatory, it is followed shortly thereafter by depressant, curare-like, antagonistic effects [2]. The resulting effects have been referred to as the *nicotinic syndrome* (Table 1).

The most striking effects of these alkaloids are observed in spinal reflexes. Convulsive activity, induced by local application of coniine to the spinal cords of frogs, was thought to be the result of direct agonist action on the motor neurons

Fig. 3 Nicotinic and muscarinic receptors of the central nervous system (CNS), autonomic nervous system (ANS), and peripheral skeletal muscles. Direct nicotinic agonists (e.g., arecoline, coniine, cytisine, lobeline, nicotine) stimulate nicotinic receptors; however, prolonged depolarization at the receptor causes eventual blockade of nicotinic receptors. ACh, acetylcholine; Epi, epinephrine; GI,

gastrointestinal; M, muscarinic receptor; N_M, nicotinic receptor at skeletal muscle; N_N, nicotinic receptor in nervous system; NE, norepinephrine; WBC, white blood cell count (From Graeme KA, Braitberg G, Kunkel DB, et al: Toxic plant ingestions. In Auerbach PS [ed]: Wilderness Medicine, 4th ed. Philadelphia, Mosby, 2001, p 111, with permission.)

Table 1 Nicotinic syndrome

Early stage	Late stage
Hypertension	Hypotension
Tachycardia	Bradycardia
Vomiting	Paralysis
Diarrhea	Coma
Muscle fasciculations	
Convulsions	

From Graem KA, Braitberg G, Kunkel DB, et al.: Toxic plant ingestions. In Auerbach PS (ed): Wilderness Medicine, 4th ed. Philadelphia, Mosby, 2001, p 1114 with permission

within the cord [16]. Based on these kinds of initial experiments, it was previously believed that the main action of coniine was strychniniform (i.e., causing convulsive activity of spinal origin) [2]. However, experiments with intact animals have shown that hemlock alkaloids and strychnine have predominantly antagonistic properties [16]. The paralyzing effect of hemlock alkaloids

is the result of the ascending neuromuscular blockade, similar to that of curare [2].

Reportedly the toxic dose in humans is approximately 60 mg of coniine, and the fatal dose is approximately 150–300 mg [17]. Ingestion of a 1 in. sq. piece of hemlock has been reported to be lethal in a child [3]. However, reports of toxic and lethal dosages are inherently prone to error.

Clinical Presentation and Life-Threatening Complications

The clinical effects after poison hemlock ingestion are biphasic. There is an initial stimulatory phase, followed by a more pronounced state of skeletal motor depression, associated with muscle weakness, paralysis, and respiratory arrest (see Table 1).

There is usually a short latent period between ingestion and onset of clinical manifestations. The first symptoms to occur are typically direct gastrointestinal irritation of the mucosa of the oropharynx, esophagus, and stomach. Gastrointestinal irritation is followed in approximately 30 min by profuse salivation, nausea, and vomiting [18], manifestations of initial cholinergic nicotinic stimulation. These episodes of emesis theoretically help to limit further exposure and toxicity.

Cardiovascular effects are typically minor. Large doses of coniine, λ -coniceine, and *N*-methyl coniine in isolated animal heart preparations cause decreased inotropy [16]. However, these effects are not seen in intact animals. In the late stages of significant poison hemlock ingestion, bradycardia, hypotension, and shock may occur.

Fasciculations of skeletal muscle and tonic-clonic contractions of separate limbs are characteristic during the initial excitatory phase. These skeletal motor effects are mediated by spinal cord and neuromuscular junction stimulation and may lead to rhabdomyolysis [2, 7]. In several cases with rhabdomyolysis, this was associated with myoglobinuria and renal failure; all these cases were due to secondary poisoning following consumption of birds that had eaten hemlock and, where tested, had high coniine levels [7].

The excitatory phase is followed by ascending muscular weakness and paralysis, with painful hypotonic skeletal muscles [7]. Affected individuals are often lethargic, and muscle weakness may lead to respiratory arrest requiring mechanical ventilation. Respiratory failure can be prolonged, lasting up to two weeks or in less-severe cases may recover completely in as little as 24 h [19, 20]. Death is usually secondary to progressive paralysis and respiratory arrest. Severe toxicity treated with ventilatory support and supportive care has led to recovery without sequelae [3].

Diagnosis

Poisoning by poison hemlock should be a diagnostic consideration in any patient with nicotinic signs and symptoms (see prior section) or

ascending paralysis after ingestion of “plant material.” No specific diagnostic tests are routinely available.

Signs of rhabdomyolysis (myoglobinuria and serum creatine phosphokinase elevations) are often present [21]. Transient elevations in liver enzymes often occur, but typically resolve as the patient recovers [21].

Alkaloids from poison hemlock are excreted by the lungs and kidneys, giving the breath and urine of poisoned animals a “mousy” odor characteristic of the plant. Analysis for coniine can be performed on urine or serum samples. The most commonly useful method for diagnostic confirmation is obtaining a portion of the plant that has been ingested. Analysis of the plant specimen by gas chromatography–mass spectrometry for the presence of the piperidine alkaloids confirms the diagnosis. Variable results have been demonstrated with mass spectrometry utilizing patient urine, blood, and serum [1, 19, 22, 23]. Analysis of cerebrospinal fluid has also been suggested [19]. In cases in which poisoning has occurred after ingestion of toxic bird flesh, coniine has been isolated from the animal specimens [7].

Treatment

There is no specific antidote for poison hemlock. Supportive care is the mainstay of treatment. If the patient presents early after ingestion, gastrointestinal decontamination with orogastric lavage may be considered because of the potency of these toxins (Level III evidence). Some clinical toxicologists recommend a dose of activated charcoal in the hope that it may decrease toxin absorption if it can be administered within 1 h of ingestion, although there are no data showing that this, or lavage, alters the clinical course or outcome. Mechanical ventilation may be required for patients who are severely poisoned. In one case series of 11 hemlock-poisoned patients, three required ventilatory support, and all three subsequently died [7]. The use of forced diuresis, hemoperfusion, and hemodialysis has been reported, but no clinical or experimental support is available for these techniques [7] (Level III).

Aggressive volume replacement with maintenance of brisk urine output is indicated in patients at risk for rhabdomyolysis. Vasopressor agents are required when there has been an inadequate response to volume resuscitation. Bradycardia can be treated per standard protocols. Based on the time frames for which toxicity would be expected, patients not exhibiting systemic signs or symptoms after 6 h of ingestion may be safely discharged home.

Indications for ICU Admission in Poison Hemlock Toxicity

Respiratory depression
Seizure-like activity
Change in mental status
Large ingestion
Pediatric patients with signs of ingestion

Special Populations

Animal studies suggest potential teratogenic effects associated with chronic exposure to poison hemlock. Observations in different animal species have found malformations predominantly of the limbs, including limb rotation; permanent flexure of the carpal or elbow joints, with or without scoliosis; and sometimes cleft palate and lip [15]. No human data are available regarding teratogenicity.

Common Misconceptions About Poison Hemlock

1. Poison hemlock is nontoxic.
2. Poison hemlock is the same as water hemlock (see ► [Chap. 115, “Water Hemlock”](#)).

Key Points in Poison Hemlock Toxicity

1. Ingestion of any part of the plant can lead to severe toxicity.
2. The main alkaloids are coniine and λ -coniceine.

3. Patients with overdoses present with nicotinic and curare-like symptoms.
4. No specific antidote is available.
5. Treatment is supportive without specific antidotes.
6. With survival, there are typically no long-term sequelae.
7. There are possible teratogenic effects.

Toxalbumins are complex proteins found in certain plant species that are toxic when ingested, inhaled, or administered parenterally. The most common plants containing toxalbumins are *Ricinus communis*, *Abrus precatorius*, and *Robinia pseudoacacia*. Although *R. communis* and *A. precatorius* concentrate the toxin within their seeds, the toxic lectins of *R. pseudoacacia* are found in the bark, seeds, leaves, and roots of the plant. The toxalbumins are summarized in Table 1. The primary toxins in these plants are ricin, abrin, and robin. They are classified as ribosome-inactivating proteins (RIP) and will be described in further detail later in the chapter.

***Ricinus communis* (Castor Bean)**

R. communis is native to Mexico and Africa and is easily cultivated in throughout the United States for castor oil, use in cosmetics, industrial lubricants, and paints, as well as an ornamental plant; it also grows wild quite ubiquitously. These large, leafy plants can grow 10–12 ft and produce brown spiculated pods, each containing three hard, shiny, almond-shaped brown striped or spotted seeds (Fig. 1). The seed is composed of three components: castor oil, which contains ricinoleic acid; pulp, which is rich in glycoproteins; and a fibrous portion, which contains the highest concentration of the toxalbumin ricin, up to 5% by weight [3]. The seeds also contain a separate toxin, a red cell agglutinating protein [8–10].

The findings and conclusions in this chapter are those of the author and do not necessarily represent the views of Centers for Disease Control and Prevention.

Stillmark, who found that the seed extract caused red blood cell agglutination, originally identified ricin in 1888. Ricin toxin gained notoriety in 1978, when a Bulgarian journalist for the British Broadcasting Company and political dissident, Georgi Markov, was stabbed in the thigh with the point of an umbrella at a bus stop near Waterloo Bridge. Days later he succumbed to multisystem organ failure and on autopsy, in Markov's leg, a small, perforated, metallic pellet was found that was presumed to contain ricin [11]. Also that year, a second Bulgarian émigré is said to have experienced a similar attack with a

similar pellet removed from his skin [12]. Ricin was also presumed to be involved in the second incident based on pellet's internal diameter and the clinical manifestations, but it was never confirmed due to limitations of laboratory testing at the time.

R. communis is grown in ornamental gardens and as a houseplant, but it is cultivated primarily for the production of castor oil, with more than one million tons of seeds harvested each year. Its seeds, as well as those of *Abrus precatorius*, are also incorporated into necklaces, rosaries, and other decorative items imported from South America and Africa. Many cases of ricin poisoning result from children unintentionally ingesting these colorful seeds [3, 6, 7, 13–15].

Castor seeds have been used for centuries in the treatment of various medical conditions. Some cultures have used this seed to treat leprosy and syphilis or as a cathartic. Modern medicine has experimented with ricin in pain control and in the prevention of graft-versus-host disease and as a cancer chemotherapeutic agent [8, 16–19].

Because ricin is one of the most potent poisons in the plant kingdom, it has been produced by governments for use in biologic weapons [12, 13, 20–25]. It has been tested since the 1940s by the United States, but in 1989, 10 L of concentrated weapons-grade, aerosolizable ricin was

made in Iraq for payload in artillery shells [13, 25]. Owing to this threat, the United States Army Medical Research Institute of Infectious Disease, congressional hearings, and government warnings have implicated ricin as a potential biologic warfare agent, and it is now designated as a select agent [26].

Abrus precatorius

A. precatorius is a green vine native to India, South America, Florida, and the Caribbean. This vine produces light purple or white flowers and 3 cm long pods each containing three to five oval, hard, glossy seeds approximately 5 mm in diameter. The seeds may be red with a black center, black with a white center, or white with a black center (Fig. 2). Abrus seeds, also called jequirity pea, Indian bean, crab's eye, rosary pea, and Buddhist's rosary, are used primarily in ornaments, jewelry, and other decor. The seed contains *N*-methyltryptophan, abric acid, and the toxin abrin [3, 6, 7]. Like ricin, *A. precatorius* seeds contain two types of toxins, abrin, a toxalbumin that is a RIP, and a heterotetrameric protein agglutinin, APA-1. The LD₅₀ for abrin by injection in humans is estimated to be approximately 20 mcg/kg and by inhalation is 3–4 mcg/kg. APA-1 has been studied in animals by intraperitoneal injection and has an estimated human LD₅₀ of 5 mg/kg.

Fig. 2 *Abrus precatorius* seeds (From New Leaf Graphics, Port St. Lucie, FL)

***Robinia pseudoacacia* (Black Locust Tree)**

R. pseudoacacia, commonly known as the black locust tree, grows to 30 m tall and 3 m in diameter and has deeply furrowed bark that is gray on the outside and creamy yellow on the inside. This tree is native to North American and found primarily in the United States, Appalachian and Ozark Mountains, as well as in areas of Canada, and Northern Mexico. The genus *Robinia* originally was named after Jean Robin, the herbalist to the kings of France during the sixteenth century who introduced this hardwood to Europe. Because of the strong bark, these trees are used primarily for furniture, mine timbers, boat ribs, fencing, and strip mine reclamation. The Cherokee Indians used this plant as a purgative, as a laxative, and for toothaches. The bark and roots contain five major flavonoids, including the toxalbumin robin [4, 7].

Biochemistry and Pharmacology

The toxalbumins ricin, abrin, and robin destroy cells by inactivating eukaryotic ribosomes. They are classified as RIPs or ribosome-inactivating proteins. Their structure, similar to those of botulinum, tetanus, diphtheria, and cholera toxins, consists of two subunits that, in the case of ricin and abrin, are joined by a disulfide bond. Ricin has a total weight of 60–66 kDa, depending on the isoform, and is divided into a B subunit and an A subunit [10, 27, 28]. The B subunit binds to glycoproteins on the surface of the cell, enabling the toxin to enter, then the A subunit, which is an *N*-glycosidase, removes single adenine residues on the 28S ribosomal RNA loop within the 60S subunit. This adenine depurination prevents polypeptide chain elongation, ultimately inhibits protein synthesis, and finally leads to cell death [8, 10, 18, 27, 29]. One molecule of ricin can deactivate up to 1,500 ribosomes/min ($K_{CAT} = 1,500 \text{ min}^{-1}$) [18].

Although apoptosis is one mechanism by which ricin causes its toxicity, there is evidence of direct necrosis from ricin by unknown mechanisms. Animal studies demonstrate concomitant systemic tissue injury from the resulting

Table 2 Comparative median lethal dose of toxins in laboratory mice

inflammatory cascade with activation of a myriad of pro-inflammatory cytokines including tumor-necrosis α , interleukin 1 β , IL-1, c-FOS, c-JUN, NF- κ B, and mitogen-activated protein kinase, among others [30–32]. The inflammatory response can lead to overproduction of oxidative species that can cause gaps in the endothelial tight junctions and poor membrane integrity. The subsequent migration of leukocytes to the site of injury can result in further tissue damage. This inflammatory process can also contribute to poor tissue repair mechanisms and excessive fibrosis in the survival phase, which, particularly if there was inhalational exposure, can subsequently lead to fibrosis and increased morbidity [32–34].

R. communis has two toxins in the fibrous portion of its seed: *R. communis* agglutinin (RCA I, RCA120) and ricin (RCA II, RCA60), each with a 60–66 kDa domain [8, 9]. In contrast to ricin, *R. communis* agglutinin is a weak cytotoxin but a powerful hemagglutinin. This ricin agglutinin is not absorbed enterally, but intravenous administration can result in red blood cell agglutination and hemolysis [8, 9].

Table 2 lists the LD₅₀ of selected toxalbumins.

Clinical Presentation

The clinical presentation of abrin and ricin toxicity depends on the route and magnitude of exposure. The most common route is oral, by unintentional ingestion of ornamental or jewelry seeds or eating the seeds whether intentionally or not. Inhalational or injection exposures are possible, particularly in the setting of biologic warfare or secondary to

Table 3 Frequency of clinical manifestations after ricin ingestion, 1900–1985

Clinical manifestations	Cases (%)
Vomiting	84
Diarrhea	83
Dehydration	35
Shock	27

homicidal or suicidal actions. Hypersensitivity reactions can occur by either inhaled or dermal exposure to the seed’s pomace remaining after the castor oil is pressed from the seeds [35, 36].

Oral ingestion of abrin and ricin can produce biphasic toxicity. The first, or local, phase can present with mucosal irritation in the oropharynx; however, lack of this finding does not rule out an ingestion. Rarely, more severe corrosive-type lesions can be present within the GI tract. The castor seeds are reportedly quite bitter in taste; however, purified ricin has little to no taste. Clinical manifestations usually present within 6 h of ingestion but it can be delayed up to 12 h, and rare cases exist with onset outwards of 24 h after exposure, with most patients developing nausea, vomiting, diarrhea with or without hematochezia, and colicky abdominal pain [37, 38]. Challoner and McCarron [39] reviewed documented ricin ingestions and found that most patients experienced primarily gastrointestinal complaints (Table 3). Patients typically experience significant GI fluid losses leading to dehydration, electrolyte imbalances, and eventually, if not adequately addressed, hypotension, shock, and circulatory collapse. Hypovolemic shock and multiorgan involvement represent the second, or systemic, phase of toxicity. In a study of 424 cases of castor seed ingestion, 14 developed fatal hypovolemic shock from intestinal fluid losses [38]. Liver failure can result from direct hepatotoxicity and shock liver [3, 37, 38]. Hemolysis, kidney failure, splenic necrosis, seizures, and cardiac

dysrhythmias have been described [3, 15, 37–39]. On autopsy, diffuse intestinal hemorrhage has been reported. Involvement of lymph nodes and lymphatic tissues is usually noted. Histology after ricin exposure in both animals and humans is consistent with both direct cellular necrosis as well as apoptotic cell death [3, 33, 34].

Variations of this biphasic presentation have occurred, with cases of only mild gastroenteritis and one case of an infant developing fulminant liver failure without previous gastrointestinal manifestations [15, 37, 38, 40]. Which patients progress to the second phase of toxicity is difficult to predict on the basis of the number of seeds ingested; however, patients who have 3–4 days of progressive diarrhea and large fluid losses are likely to develop shock [37, 38]. Aggressive symptomatic and supportive care is the mainstay of treatment. There has been only one known reported death from ricin ingestion in the United States in almost 50 years because of excellent intensive supportive care. Unlike the ingestion of ricin, the exposure to ricin by inhalation or injection is expected to cause severe toxicity and increased mortality.

Inhalational exposures, primarily in settings of biologic warfare, produce a different presentation from oral exposure. Based on data collected during a sublethal unintentional aerosol exposure in the 1940s, fever, cough, dyspnea, chest tightness, and arthralgias develop after 4–8 h. Development of profuse sweating is usually the hallmark of resolution [13]. In animals exposed to large doses, they developed diffuse necrotizing bronchiolitis, alveolitis, and fibropurulent infiltrative disease with noncardiogenic pulmonary edema and died from hypoxia in 36–72 h [32–34]. Monkeys exposed to sublethal doses of aerosolized ricin still developed multifocal interstitial pneumonia, fibroplasia and fibrosis, interstitial pneumonitis with hyperplasia, and some patchy pulmonary edema. Of note, the monkeys also developed extrapulmonary involvement of their lymphatic tissues [33, 34].

Injection of crystalline or liquid abrin and ricin can produce local pain, mild dyspnea, and cough or wheeze. Progression to multiorgan failure and death can occur [3, 11, 12, 37, 38, 40]. In animal

models, IV or IP administration invariably leads to widespread necrosis of lymphoid organs and involvement of liver, kidneys, heart, and GI tract. Most animals die of multisystem organ failure, which is consistent with findings from the scattered case reports of people exposed to ricin by the intravenous or intramuscular route [3, 37–40]. Ingestion of *R. pseudoacacia* bark results primarily in gastroenteritis, similar to that described for ricin and abrin. Some reports of central nervous system involvement have been described. In unintentional ingestion by two horses, one showed alternating phases of somnolence and excitation, mydriasis, and decreased sensation to the head [4]. Vertigo, muscle twitches, cardiac dysrhythmia, and weakness also have been described [4, 37].

Hypersensitivity reactions to *R. communis* seeds have been well described in response to dermal and inhalational exposures. Garcia-Gonzalez and colleagues [41] showed the role of *R. communis* as a pneumoallergen, causing primarily respiratory and nasal symptoms. In sensitized industrial castor seed workers, allergic dermatitis, rhinitis, asthma, and anaphylaxis have been recognized [3, 14, 35, 36]. One representative case report described facial itching, periorbital edema with complete eyelid closure, and urticarial wheals after touching the powder in a broken ricin seed from a necklace [14]. Residents of neighborhoods surrounding castor oil plants exposed to high levels of castor seed pomace dust in the air have higher than average number of reports of allergic rhinitis and levels of ricin antibodies [35, 36]. Diagnosis depends primarily on history of exposure and is important for the avoidance of subsequent, more severe anaphylactic reactions.

Pathophysiology

The effects of ricin and abrin exposure can vary from mild gastroenteritis to multiorgan failure and death. The type and severity of a patient's response depend on the amount and route of exposure: ingestion, inhalation, or injection. Each route can evoke specific and early manifestations, but all can result in multisystem failure.

When ricin is injected intramuscularly, local necrosis of the soft tissue or regional lymph nodes can occur. If the toxin is absorbed systemically or injected intravenously, multiorgan failure can ensue. *R. communis* agglutinin causes hemagglutination and intravascular hemolysis by binding to glycoproteins on red blood cells [8, 9, 36]. The by-products of hemolysis can occlude the renal tubules, resulting in acute tubular necrosis and subsequent renal failure. Ricin can bind and damage the lung's vascular endothelium, resulting in noncardiogenic pulmonary edema and hypoxia. Fulminant liver failure may result from direct hepatotoxicity as well as indirectly from hypovolemic shock [34, 37–41]. In vitro experiments with mice have shown that peritoneal injection of ricin at low doses results in multifocal necrosis in parenchymal organs, and larger doses produce hemorrhage in visceral and serous cavities with subsequent death from organ failure and shock [40].

Ingestion of ricin, abrin, or robin can cause mild to moderate corrosive-type injuries and gut endothelial damage, resulting in ulceration and loss of fluid and blood [3, 37–39]. The ensuing bowel wall edema and decreased intestinal absorption can lead to diarrhea, dehydration, and hypovolemic shock. With systemic absorption, these toxins can cause cytotoxicity via both direct cellular necrosis and induction of apoptosis to any organ, such as the pancreas, spleen, liver, heart, and kidney [3, 37–40].

Inhalation of ricin is another method of exposure that is potentially dangerous. The airways can develop necrotizing lesions resulting in tracheitis, bronchitis, bronchiolitis, or interstitial pneumonia. These conditions can progress to perivascular and alveolar edema, damaging infiltrative and necrotizing bronchiolitis and pneumonitis, and subsequent hypoxia requiring mechanical ventilation [13, 32–34, 41].

Clinical Effects and Life-Threatening Complications

The modern case fatality rate is estimated at less than 2% with the availability of excellent supportive care. Worbs et al. [38] report a summary of

worldwide cases from the available literature with a summary of 875 ingestions and only 13 reported fatalities from 1900 to 2011 resulting in a case fatality rate of 1.5%. However, the fatality rate for injections is considerably higher at 45.5% [38]. Intravenous administration can produce death more quickly and at lower doses than can ingestion; inhalation can also be quite toxic if the particle is of sufficient size to reach the lower airways and the amount sufficient to cause toxicity and injury. Nearly all of case fatalities reported in the modern literature are from injection of the toxin [37, 38].

For oral administration, data have been variable on the number of seeds required for serious sequelae. Eight to 20 ricin seeds in adults and as few as three in children have been reported to produce death; however, mastication of the seeds is required to cause toxicity [3, 37–39]. In one case report, a patient swallowed more than 30 ricin seeds and survived, whereas other authors have reported ingestions of three seeds that resulted in only a mild gastroenteritis [3, 38, 39]. This variability in toxicity likely depends on how well masticated the seed is or plant to plant variation in seed toxicity because the concentration or the type (isoform) of the toxin can vary due to factors such as growing conditions, plant maturity, and plant variety or cultivar [9].

Ricin toxin can be inhaled as a lyophilized powder, although creating a “weaponized” size particle is extremely difficult to achieve. The aerosolized dose that was fatal in 50% of exposed mice (LD₅₀) is 3–5 µg/kg [3]. Based on this finding, approximately 8 t of toxin would have to be produced and deployed to significantly affect a human population living in an area of 100 km². Based on extrapolated data from studies in monkeys and other animals as well as human case reports, the estimated LD₅₀ in humans is 5–10 mcg/kg by inhalation and 1–20 mg/kg by ingestion [3, 13, 33, 34].

Experiments with mice show that the LD₅₀ for intraperitoneal administration of ricin and abrin varies from 2–20 mcg/kg, producing death within days [42]. Subcutaneous administration of 0.1–0.2 mg of abrin extracts into mice resulted in death within 24–48 h, and 0.2 mcg can induce

Table 4 Analytical methods and target analytes used in presumptive and confirmatory testing to detect ricin in selected matrices

Matrix	Presumptive	Confirmatory

Urine	LC-MRM-IDMS (ricinine, abrine) [47, 48]	

^aAbbreviations: *LC-LTQ/FT-ICR MS* liquid chromatography – linear quadrupole ion trap/Fourier transform ion cyclotron resonance mass spectrometry, *LC-MRM-IDMS* liquid chromatography – multiple reaction monitoring – isotopic dilution mass spectrometry, *PCR* polymerase chain reaction, *MALDI-TOF/TOF MS* matrix assisted laser desorption ionization – tandem time of flight mass spectrometry, *TRF IMA* time-resolved fluorescence immunoassay

red blood cell agglutination in vitro [6]. Because a lethal dose of these toxins can be delivered in a small concentration, there is concern for their potential use to commit suicide or homicide.

Diagnosis and Detection

Diagnosis of toxalbumin poisoning depends primarily on the history of illness. If the patient presents with the seeds for identification, protective gloves should be used when handling to avoid possible contact dermatitis. Because there are many causes of diarrhea and the exposure to a toxalbumin might not be apparent upon presentation, the diagnosis is often delayed or made incorrectly.

There are various strategies to detect ricin in environmental samples and clinical specimens that can aid the diagnosis of ricin poisoning. These approaches are detection of proteins, DNA, enzymatic activity (*N*-glycosidase), and amino acids (peptides) that are characteristic of ricin. The level of confidence that the test result is specific for ricin (*Ricinus communis* agglutinin II (RCA II, RCA60)) depends on the analytical method and test analyte (Table 4) [43–54].

For example, a positive test result from an immunoassay method is considered presumptive evidence for the presence of ricin (RCA60) because it can also

detect the less toxic protein *Ricinus communis* agglutinin I (RCA I, RCA120). Similarly, the detection of certain peptides or *N*-glycosidase activity is considered presumptive evidence for the presence of ricin because the same peptide sequence can be found in ricin and RCA120, and *N*-glycosidase activity is common among ricin, RCA120, and ribosome-inactivating proteins [9, 49].

The detection of ricinine is also presumptive evidence for the presence of ricin from a natural source [47]. The lack of detection of ricin DNA or ricinine does not exclude the presence of purified or protein isolates of ricin in the sample. The presence of ricin is confirmed when peptides specific to ricin are detected in the sample [9, 49]. The confirmation of a positive test result for ricin is made at a reference laboratory.

Virtually no testing will be available without involvement of law enforcement and public health agencies. It is advised to consult with these agencies early regarding patients with suspected poisonings from ricin or other toxalbumins. Depending on the circumstances, environmental testing may be needed and testing of close contacts of the patient as well, if they are symptomatic and under treatment. Healthcare providers are advised to contact their local public health department or Centers for Disease Control and Prevention when they anticipate the need to test for the presence of ricin or abrin [20, 21].

Treatment

If only one or two castor seeds were ingested and the exposure was unintentional, the patient can be discharged after remaining without signs or symptoms for 6 h while under observation. If more than two seeds were eaten or if clinical manifestations have developed, the patient should be admitted. Because of abrin's higher potency than ricin, any amount of oral exposure to this seed is potentially lethal, and patients should be admitted.

If a patient presents within 2 h of oral ingestion, gastric decontamination with activated charcoal can be considered, although it has not been studied in this setting, and it is unknown whether activated charcoal alters the clinical course or affects outcome in these ingestions. Precautions, such as a protected airway, need to be observed when administering activated charcoal to patients [55]. There is no role for cathartics. Whole-bowel irrigation after toxalbumin ingestion cannot be recommended at this time because it has not been shown to be helpful, although this has not been studied extensively.

Supportive measures are the mainstay of treatment of abrin, robin, or ricin toxicity. Aggressive fluid resuscitation should be started early for treatment of dehydration and prevention of hypovolemic shock and acute tubular necrosis. Admitted patients should be observed for 24–48 h for evidence of hypovolemia, hepatotoxicity, renal failure, and hemolysis with daily or twice-daily laboratory evaluation.

For inhalational exposure, the patient's respiratory status and pulse oximetry should be monitored. Patients with diarrhea persisting for more than 3–4 days, hepatotoxicity, or respiratory compromise should be monitored in an intensive care unit. Patients who have been injected with ricin or abrin have a high risk for systemic toxicity and should be monitored in an intensive care unit. Hypovolemic shock should be treated with intravenous crystalloid fluids and vasopressor support, if necessary. Pulmonary edema may require intubation and mechanical ventilation. Owing to toxin-induced dysrhythmias, continuous cardiac monitoring should be employed. Brisk urine output should

be maintained to prevent acute tubular necrosis; however, forced diuresis should not be performed.

In the setting of massive intravascular hemolysis, we recommend maintaining a rapid urine flow (150 mL per hour) and avoiding aciduria to limit hemoglobin precipitation and schistocyte-mediated renal tubular damage. Patients with inhalational exposure and those in multisystem organ failure are at increased risk for pulmonary edema, so their respiratory status needs to be monitored closely during large volume fluid resuscitation. There are no data to support the use of loop diuretics, atrial natriuretic peptide, or mannitol in the treatment of acute tubular necrosis caused by heme compounds. Dialysis may be required if uremia or refractory metabolic acidemia ensues.

Indications for ICU Admission in Toxalbumin Poisoning

Significant hepatotoxicity or other evidence of end organ failure

Diarrhea for >3–4 days with dehydration

Respiratory distress, failure, or significant hypoxia

Exposure by injection

Systemic inflammatory response syndrome/shock

Massive hemolysis

Ricin and abrin are water soluble and metabolized by the liver; consequently, hemodialysis or forced diuresis does not enhance their elimination. In a case series from China, seven children with clinical manifestations from unintentional ingestion of castor seeds appeared to improve with plasma exchange (plasmapheresis) [56].

An antidote for ricin toxicity is not currently available. Some novel treatments under investigation include use of *N*-acetylcysteine (NAC) and liposome-encapsulated NAC. An animal study with NAC showed some promise in mitigating the hepatotoxicity of the ricin A subunit (chain). NAC's potential benefit in this setting might be mediated through its anti-inflammatory effects and inhibition of lipopolysaccharide-induced activation of NF- κ B, which mitigates

downstream inflammatory cascade [57]. No human trials have been performed with NAC for ricin toxicity. Other novel therapies that have been studied in mice include dexamethasone and the antioxidant vitamin E. Although neither agent prevented death, both extended survival time in pretreatment trials [58]. An in vitro study demonstrated milk, lactose, and galactose inhibited binding of the ricin B subunit (chain) to cell surfaces and prevented entry of the toxin into cells [59].

Vaccines for ricin and specific antibody therapy have been in development for several years and they have had some significant successes; however, none of them are commercially available at this time [60–62]. People at high risk for exposure to ricin, such as military personnel and first responders, might benefit from vaccine therapy when it becomes available. Directed antibody therapy, with humanized animal derived Fab and recombinant antibodies, has been very promising in in vitro and in vivo studies [63–65]. For example, animals have excellent protection from ricin exposure when they received such treatment in a timely fashion even after inhalational exposure [61–64]. Other non-antibody small molecules and other cellular protein inhibitors are currently under investigation to identify alternative mechanisms to inhibit the protein-mediated effects of ricin [66].

Special Populations

Pediatric Patients

- Incidence of toxalbumin exposure is high in children, given their attraction to the decorative, colorful seeds.
- Oral mucosal irritation and GI mucosal lesions seen with ricin exposure can resemble viral exanthems and be misdiagnosed easily.
- As a result of the high respiratory rate in children, an aerosolized ricin exposure can deliver a high dose of the toxin and increase the risk of pulmonary manifestations.

- Children can progress to hypovolemic shock more readily than adults after gastrointestinal fluid losses.

Key Points in Toxalbumin Poisoning

The most common route of toxicity is unintentional ingestion; intravenous and inhalational delivery can produce death quickly and at low doses.

Diagnosis of toxalbumin toxicity is primarily by history.

Hypersensitivity reactions have been described for dermal and inhalational exposures.

Gastroenteritis, after seed ingestion, is the most common and usually the first manifestation; multiorgan failure can ensue.

Supportive measures are the mainstay of treatment.

Water hemlock belongs to the family Apiaceae (Umbelliferae). The genus *Cicuta* includes the species spotted water hemlock (*C. maculata*), Western water hemlock (*C. douglasii*), and northern water hemlock also known as European water hemlock (*C. virosa*), *C. bolanderi*, *C. bulbifera*, *C. californica*, *C. curtissii*, *C. mackenziana*, *C. occidentalis*, and *C. vagans* (Figs. 1, 2, and 3). The active toxic compound in water hemlock is cicutoxin. The hemlock water dropwort (*Oenanthe crocata*) belongs to the family Apiaceae (Umbelliferae), genus *Oenanthe*. It is native to Europe but has been introduced to some parts of the United States. It lacks the chambered root of the *Cicuta* spp. and produces oenantheotoxin, a constitutional isomer (a compound that has the same molecular formula but a different structural formula) of cicutoxin.

The various species of *Cicuta* and *Oenanthe* have approximately equivalent clinical toxicity at similar stages of plant growth, producing virtually identical clinical manifestations in poisoning, and, therefore, will be discussed as a single group. Common names of these plants include cowbane, children's bane, poison parsnip, five-fingered root, dead men's fingers, death-of-man, wild parsnip, snakeweed, beaver poison, muskrat weed, spotted hemlock, spotted cowbane, musquash root, false parsley, poison hemlock, wild carrot, fever root, mock-eel root, spotted parsley, cique vireuse, and carotte à moreau.

Water hemlock species are biennial or perennial plants that grow to a height of 6–8 ft with

narrow, compound leaves that have serrated edges. Purple spots (“macules”) may be visible on the hollow and chambered stalk. Small fragrant white flowers develop as compound umbrellalike formations (umbels) that typically blossom in June or July. *Cicuta* and *Oenanthe* species grow only in habitats with continuous water, such as swamps, lakesides, stream banks, drainage ditches, and marshes. *Cicuta* spp. have thick, tuberous roots, which are often bundled with as many as five or six roots. When cut, they yield an oily yellow sap that has an odor of parsnips and rapidly turns brown on contact with air. When the thickened underground portion of the stem and roots are sectioned sagittally, characteristic multi-layered air chambers separated by pith diaphragms are seen [1] (Fig. 4). These chambers are not as distinct in the spring as they are later in the season [2]. All parts of the plant are

Fig. 4 Western water hemlock (*C. douglasii*). Note chambered root and hollow stalk (Photo: William Follette (Lagunitas Creek, Marin County, CA). Accessed at: <http://plantid.net/Slideshow/ShowPhotos.aspx>)

considered poisonous. The tuberous roots are the most toxic part, especially in the spring, prior to flowering, when they are typically the most developed. *Oenanthe crocata* roots are usually more bulbous than those of the *Cicuta* spp. and are solid rather than chambered. They also produce a sticky yellow, oily sap when cut [3, 4].

It is important not to confuse water hemlock with the closely related poison hemlock (*Conium maculatum*), which has a similar appearance. Poison hemlock also belongs to the family Apiaceae (Umbelliferae) and has small white flowers in umbellate clusters similar to those of water hemlock. However, poison hemlock has wider leaves that have three to five divisions and a single tap root that is non-chambered. The root of poison hemlock also yields an oily, yellow sap when cut. *Conium maculatum* was imported to North America from Europe and is now found in the same geographic range as water hemlock, throughout the United States and southern Canada. Poison hemlock occurs globally due to introduction into new areas, with reports from North and South America, Europe, Africa, Asia, Australia, and New Zealand, but appears native to Europe, Western Asia, and North Africa. In contrast, water hemlock appears to be restricted to the Northern Hemisphere, notably Europe and North America. The habitat for poison hemlock differs from water hemlock in that it is typically drier (e.g., roadsides, fields, and ditches). The active toxic principles in poison hemlock, including coniine,

N-methyl coniine, conhydrine, λ -coniceine, and pseudoconhydrine, produce a different spectrum of clinical effects than the toxins found in water hemlock. Poisoning from water hemlock manifests primarily as vomiting and seizures that occur within an hour of ingestion, whereas poison hemlock presents with initial gastrointestinal upset, then autonomic and somatic stimulatory features that are followed by central nervous system (CNS) depression, ascending paralysis, and bradycardia. A complete discussion of poison hemlock poisoning is given in ► [Chap. 113, “Poison Hemlock.”](#)

Water hemlock has also been mistaken for other members of the Apiaceae (Umbelliferae) family that are edible, such as *Daucus carota* (carrots), *Pastinaca sativa* (parsnip), “wild parsnips,” and many other wild tuberous plants that are objects of human foraging including artichokes, celery, sweet potatoes, and sweet anise [2–16]. Fatal poisonings have resulted from the ingestion of *C. maculata* that was mistakenly identified as American ginseng [17, 18]. Livestock poisoning also occurs, frequently in the spring, as water hemlock is usually located near water sources where animals graze and emerges early in the season before other forage becomes available.

Human ingestion of water hemlock roots is most often the result of ill-advised wild plant foraging by adults and/or children. Some reviews of water hemlock poisoning dating back over 100 years note that there are more cases of pediatric poisoning than adult, likely due to the fact that this population is more given to experimental ingestion of foraged plants than adults [7, 15, 19].

Biochemistry of Active Compounds

The compounds responsible for the water hemlock’s toxicity vary depending upon the species, but all belong to a class of conjugated C_{17} -polyacetylenes. These are highly unsaturated, polyacetylenic alcohols that are isomers or analogues of a 17-carbon skeleton that all include a conjugated polyacetylene system, a terminal hydroxyl group at C_1 , and an allylic hydroxyl

Fig. 5 Chemical structures of C_{17} -polyacetylenes from water hemlock

group at C_{14} [20]. Cicutoxin, isocicutoxin, cicutol, oenanthotoxin, oenanthetol, oenanthetone, and virols A, B, and C have been isolated from *Cicuta* and *Oenanthe* species. Cicutoxin was first described by Boehm in 1876 [21] and has since been extensively characterized in multiple subsequent works. The principle toxic members of this group are **cicutoxin** ($C_{17}H_{22}O_2$, *trans*-heptadeca-8:10:12-triene-4:6-diyne-1:14-diol); its isomer, **oenanthotoxin** ($C_{17}H_{22}O_2$, *trans*-heptadeca-2:8:10-triene-4:6-diyne-1:14-diol); and **virol A** (*trans*-heptadeca-8:10-diene-4:6-diyne-1:11-diol) [20, 22, 25, 26, 39] (Fig. 5). Cicutoxin and oenanthotoxin are structurally very similar and are equally toxic. Similarly, the alcohols cicutol and oenanthetol are structurally similar and are relatively nontoxic [22].

These C_{17} -polyacetylenes are found in all parts of the plants. However, the tuberous roots contain the highest concentration of toxins and are also the portion of the plant most commonly ingested. As is typical with most naturally occurring toxins, the

concentration and variety of active compounds in a given plant varies with season, geographical location, environmental conditions such as water supply and soil conditions, as well as which plant species or plant part being considered. Roots from *C. maculata* and *O. crocata* retain their toxicity long after harvesting and/or drying [25, 26]. Although cicutoxin and oenanthotoxin are relatively unstable compounds on exposure to air, light, and heat, poisonings after ingestion of dried and/or cooked roots of both *O. crocata* and *C. maculata* have been reported [3, 4, 27, 28]. Pharmacological studies by Grundy and Howarth have demonstrated marked toxicity with dried and powdered tubers of *O. crocata* [29].

The C_{17} -polyacetylenes are water soluble but can be readily extracted with organic polar solvents such as methanol, ethanol, and ethers. They can be studied in both biological and environmental samples using high-performance liquid chromatography, thin-layer chromatography, and mass spectroscopy [20, 22, 28, 29].

Fig. 6 General structure activity relationship of C_{17} -polyacetylenes from hemlock. Cicutoxin is the *trans*-isomer and isocicutoxin is the *cis*-isomer (After Uwai et al. [38], with permission)

The structure-activity relationship between C_{17} -polyacetylenes found in *C. virosa* and gamma-amino butyric acid A ($GABA_A$) receptors in rat brain cortex has been studied. Eleven C_{17} -polyacetylenes have been isolated from water hemlock root, including cicutoxin, isocicutoxin, and virols A, B, and C [20, 23, 24]. By synthesizing more chemically stable structural analogues, the structural requirements for toxicity have been determined. The length of the π -bond conjugation system and the geometry of the double bonds are critical for toxicity. This is exemplified by comparing the LD_{50} of cicutoxin, with all *trans* double bonds, and that of isocicutoxin, which has a *cis* configuration at its C_8 - C_9 double bond (Fig. 6). The LD_{50} values of cicutoxin, isocicutoxin, virol A, and picrotoxin in a mouse model (intra-peritoneal) are 2.8, 38.5, 9.5, and 9.8 mg/kg, respectively [20, 23, 24]. Other C_{17} -polyacetylene analogue studies showed that the terminal *O*-functional group and the allylic alcohol were also essential for toxicity [20].

Pathophysiology

The primary toxic effects of water hemlock, namely, severe and recurrent seizures, result from its $GABA$ antagonist action in the CNS. Normally, agonism of $GABA_A$ receptor-linked ion channels results in the influx of chloride into the neuron. This hyperpolarizes the neuron thereby inhibiting depolarization. Cicutoxin and the other toxic C_{17} -polyacetylenes are believed to inhibit this hyperpolarization, thus allowing depolarization of neurons to go unchecked, leading to

seizures. This effect is dose dependent, as the severity of poisoning has been found to be directly related to the amount of the plant (usually the root) ingested.

Grundy and Howarth noted that seizures produced by oenanthotoxin were indistinguishable from those produced by picrotoxin [29]. Picrotoxin is a noncompetitive indirect $GABA$ antagonist and binds to a specific site, distinct from the $GABA$ itself, on the $GABA_A$ chloride channel [30]. Pretreatment with one-tenth the convulsive dose of an extract of *C. douglasii* decreased the convulsive dose of picrotoxin in a dose-dependent manner, but did not significantly decrease the convulsive dose of pentylenetetrazol, supporting a picrotoxin-like mechanism for cicutoxin's proconvulsant activity [31].
